Previous to 1892 Spain ranked first as a contributor, supplying in 1890 over half a million tons, the ores coming from the Bilbao district, in the northern portion of the country, or from mines located near the Mediterranean sea, in southern Spain. In 1892, however, Cuba took first rank, which position it still holds. In the earlier years Algeria and Italy were also important contributors, but lately the amount received from these countries has been small, and in some years none has been imported.

In 1889 and 1890 Greece forwarded a comparatively small amount of iron ore, some of which contained a small percentage of manganese. Newfoundland and Labrador contributed ore in 1889, 1890, and 1896.

In the year 1902 the imports of iron ore, 1,165,470 long tons, were the largest since 1890, when 1,246,830 long tons were brought to this country. Cuba was the principal contributor in 1902, supplying 696,375 long tons; the provinces of Quebec and Ontario, Canada, sent 203,824 tons; Spain, 153,527 tons; and Newfoundland and Labrador (principally Newfoundland), 81,920 tons. Smaller amounts were imported from Algeria, Belgium, British Columbia, France, Germany, and Great Britain.

Table 14 is a detailed summary of the statistics for active mines, by states and territories. Where one or two operations only were active in a state, the statistics have been combined in order not to disclose individual operations, and are presented under the head "all other states and territories." This table, in connection with Table 9, presents a synopsis of the entire iron ore industry of the United States.

DESCRIPTIVE.

The phenomenal record made in producing pig iron in the United States is illustrated by the following statement from the annual statistical report of the American Iron and Steel Association. This shows the growth in the manufacture of pig iron in the past nine years, until in the year 1902 the maximum production approximated 18,000,000 tons.

Production of pig iron: 1894 to 1902.

YEAR.	Long tons.	YEAR.	Long tons.
1894	6,657,388	1899	13,620,703
1895	9,446,308	1900	13,789,242
1896	8,623,127	1901	15,878,354
1897	9,652,680	1902	17,821,307
1898	11,773,934		

This record naturally invites attention to the materials entering into the manufacture of pig metal, the character of these materials, and the sources from which they are obtained. Fuels, iron ores, and fluxes, components of commercial pig iron, in passing through blast furnaces, produce either pig iron in merchantable form or liquid metal, to be carried to Bessemer converters or open-hearth furnaces. In 1902 an effort was made on behalf of the Canadian government in equating bonuses to iron industries, to discriminate against liquid metal being classed as pig iron, but the contention was not sustained, and commercially the entire product of blast furnaces smelting iron ore is considered and reported for statistical purposes as pig iron.

PLATE VI.—GROUP OF MINE BUILDINGS AND DWELLINGS, CLIFFS SHAFT MINE, LAKE BANCROFT, MICHIGAN.

For the production of the quantity of pig metal credited to the United States in the year 1902 there were required about 30,000,000 tons of bituminous coal (the larger portion of which was converted into coke) and about one million and a half tons of anthracite coal. In addition to mineral fuel probably 350,000 tons, or 38,000,000 bushels of charcoal were consumed in blast furnaces. About 33,000,000 tons of iron ore were fed to the furnaces, and the flux necessary to carry away the impurities of the ores is estimated at about eight and a half million tons. Therefore, to supply the blast furnaces of the United States in 1902, which produced nearly 18,000,000 tons of pig iron, there were required about 73,000,000 tons of raw materials.

In the manufacture of pig iron a considerable quantity of rolling mill cinder, roll scale, etc., is produced which is also employed practically as ore. Some "blue billy" or "purple ore," resulting from the calcination of pyrites and the residuum from roasting ferriferous and manganiferous zinc ores, are also utilized. The total amount of iron ore and of materials used as ore made available in the United States in 1902 may be approximated as follows:

	Tons.
Domestic iron ores	35,567,410
Foreign iron ores	1,165,470
Roll scale, mill cinder, blue billy, etc	1,900,000
Total	38,632,880

Some iron ore is employed for other purposes than for the manufacture of pig iron. It forms an important part of the charge of many open-hearth steel furnaces, and is used also for fix in puddling and other furnaces, for flux in silver smelting, and in making metallic paints. After making allowance for the other materials that are used as ore and deducting the quantity of ore which is applied to purposes other than iron production, the actual quantity of iron ore and materials used as ore entering into the manufacture of pig iron in 1902 is found to be, approximately, 33,000,000 long tons.

The active demand for iron ore to maintain in operation the blast furnaces of the United States, and the expectation that this demand would continue, was responsible to a great extent for the phenomenally large output of the iron ore mines in the year 1902. Large stocks of ore accumulated at or near blast furnace plants aided in swelling the total iron ore supply to figures never before reached and which may not be exceeded in the near future.

CLASSIFICATION OF IRON ORE.

Iron ore may be considered in four general commercial classes, as follows:

(1) Red hematite, including all anhydrous hematites, known by various names, such as red hematite, specular, micaceous, fossil or slate iron ore, martite, blue hematite, etc.

(2) Brown hematite, including the varieties of hydrated sesquioxide of iron, recognized as limonite, goethite, turgite, bog ores, pipe ores, etc.

(3) Magnetite, an ore in which the iron occurs as magnetic oxide and which includes some martite, mined with the magnetite. Martite is a red hematite ore which preserves to a varying extent the crystalline form of magnetite, but which is nonmagnetic or nearly so.

(4) Carbonates comprise those ores which contain a considerable amount of carbonic acid, such as spathic ore, blackband, siderite, clay ironstone, etc.

This classification is to be considered as general, the ores having various local or trade names. Thus the prevailing color or general physical appearance is used to indicate an ore, as blue, black, red, or brown, micaceous or glistening hematite. The term "specular," although more properly applied to a glistening ore, is by custom given to many dull red hematites. Other hematites receive designations according to their topographical or geographical occurrence, as "fossil," "mountain," or "valley" ore, or to the structure, as "flaxseed" ore, "slate" ore, etc. In the brown hematite class "limonite," "turgite," etc., are mineralogical terms referring to the degree of hydration, but the physical structure and appearance of some of the ores are described by the term "lump" ore, "pipe" ore, "botryoidal" ore, "needle" ore, etc. The beneficiating of brown hematites has given rise to the terms "wash" ore, "sand" ore, etc. The carbonate ores are known as spathic ore, limestone ore, blackband ore, kidney ore, etc.

The association of other substances with iron also furnishes names to certain ores, such as pyrite, pyrrhotite, ilmenite, chromite, etc., but in this discussion it is not essential that either the chemical, mineralogical, or physical features of the various ores should be considered in detail.

The early iron industry of the United States was based largely upon bog ores, limonites, or other forms of brown hematites, obtained at points convenient to the Atlantic seaboard. Magnetites also were employed at first by means of a direct process whereby, in Catalan forges, the ores were reduced and the resulting metal forged into blooms or billets without passing through the casting process; subsequently magnetites as well as hematites were smelted in blast furnaces. But the later development of the iron industry and present great importance are due largely to the use of red hematite ore.

The brown hematites and red hematites are of the same chemical composition in so far as iron oxide is the basis of the ore, the primary differences being structural and the lower percentages of combined and hygroscopic water in the red hematites. Red hematite, if free from other impurities, will yield 70 per cent of iron, and pure brown hematite, if thoroughly dried out

and calcined to eliminate all water, will also yield the same proportion of iron. But if the ores are merely dried to drive off the moisture, which differs under varying conditions, the amount of metallic iron possible in a pure red hematite is about 70 per cent, and in a pure brown hematite 60 per cent. However, iron ores seldom occur practically pure, the amounts of silica, alumina, lime, magnesia, and of such elements as manganese, chromium, sulphur, phosphorus, titanium, etc., reducing the actual percentage of metallic iron obtainable from ores.

Magnetic ores are capable of yielding in the pure state more metal than any other ores, and pure magnetite would show 72.48 per cent of metallic iron, but magnetites, like the hematites, are subject to deterioration from other elements which are present.

The fourth form of iron ore is the carbonate or spathic, in which the oxide of iron is associated with carbonic acid and generally with lime. If this carbonic acid is driven off by heat carbonate ores become practically brown hematites, but in the natural state the purest carbonate would not yield over 46.7 per cent of iron. Considerable of the early iron industry, particularly in western Pennsylvania, eastern and southern Ohio, Kentucky, and Maryland, and also to a certain extent in eastern New York, was based upon the use of carbonate ores, but because of the facts that these ores in their natural state are "lean," that they usually occur in veins that must be worked underground, often deteriorating as workings are extended, and that the ore must be roasted, the quantity of carbonate iron ores employed has been greatly reduced, until in the year 1902 only 27,642 tons were used.

In late years the quantity of magnetic iron ores utilized annually in producing pig iron has increased but slightly, although some remarkable deposits of these ores are available. But magnetites are not as readily reduced as the hematites, are often dense and hard, are liable to have an excess of sulphur, phosphorus, or titanium, or are so closely associated with the gangue matter as to make them lean, demanding that roasting or some method of concentration, either by hydraulic or magnetic separators, should be employed.

Brown hematites occur mostly in pockets or lenses, but are occasionally found in strata, often associated closely with limestone, and also more or less intimately mixed with clays and siliceous matter. Consequently, many brown hematites require washing to separate the clay and sand, and in some cases this washed ore is subsequently roasted to drive off the excess of moisture.

All methods of beneficiating ores, such as roasting, washing, and separating, add to the expense of production, and it is therefore not surprising that red hematites, which seldom require preliminary treatment, have met with general favor. This preference can also be explained by the fact that the ores are usually readily reducible, and most of those mined yield satisfactory percentages of iron. Another feature of material advantage is that many red hematites occur in large and well-defined lenses or bodies, permitting the exploiting of the deposits on a large scale by utilizing labor-saving appliances. The use of such appliances may extend from the winning of the ore at the mine to its delivery at the blast furnaces. Thus a large proportion of the red hematite ore from the Lake Superior region is never touched by manual labor. That which is obtained from open cut workings is in many cases dug by steam shovels which load the ore into standard railroad cars. In some underground mines manual labor is confined practically to directing the ore into "mills" and chutes, which discharge into mine cars, these cars being elevated and automatically dumped into bins from which standard railroad cars are loaded. In other underground operations it is necessary to shovel the ore by hand into mine cars, but thereafter labor-saving appliances are available.

Most of the ore mined in the Lake Superior region is carried in standard railroad dump cars to shipping docks, where it is dropped into bins, from which chutes convey it into the holds of vessels brought to the side of the docks. These vessels are unloaded by mechanical appliances, which deliver the ore either onto stock piles or into standard railroad cars, which carry it to the blast furnaces. At the blast furnace plants there are equally satisfactory mechanical appliances, such as car dumpers, which empty a 100,000-pound car by reversing it, or traveling bridges, fitted with large buckets, which transfer to bins or to stock piles the ore dumped from the cars. These devices are so perfected that only a small amount of ore is touched by hand from the time it leaves its native bed until it passes into the blast furnace, and while they are most in evidence in the Lake Superior region they are in use in connection with important iron ore mines in other portions of the country.

DISTRIBUTION OF ORE DEPOSITS.

The distribution of iron ore throughout the United States is general; there is no state in which iron ores of some kind are not found in considerable quantities, but all are not available for use.

In some cases the ores are too lean, that is, carry too small a percentage of iron; in others deleterious elements, such as phosphorus, sulphur, silica, and titanium, are in excess. Some deposits are too far from desirable fuel, or too inconvenient to blast furnaces, to make their immediate utilization practicable; others are in small bodies or veins, or are scattered over too large areas to make their exploitation profitable. It is probable that some of the undeveloped deposits may be exploited in

PLATE VII.—CLEVELAND LAKE MINE, MARQUETTE RANGE, MICHIGAN, LOOKING EAST.

the near future as the development of newer sections of the country makes fresh demands for iron, or as the extension of railroad facilities and water transportation brings the ores and fuel into convenient association. Improvements in smelting and fluxing ores, which are now considered undesirable because of the presence of some of the elements mentioned above, may also make the production of satisfactory metal from these ores a commercial possibility. While the manager of a smelting plant can obtain ores high in iron, or those which need no beneficiating treatment, at prices which permit him to produce metal at a satisfactory profit, he can not be expected to consider favorably supplying the blast furnaces under his direction with inferior raw material. But the rapid increase in the output of the blast furnaces to meet the growing demands of a developing country may in the near future encourage the utilization of ores which are now considered undesirable.

While the statistical data is reported by states, except in such cases as would disclose individual statistics, a presentation of the industry according to prominent districts is offered as of interest, for the lines dividing states are lost in anything affecting the industry of the nation. The statistics for these districts are presented in summarized form in Table 11.

The Lake Superior region.—The greatest development of iron ore deposits in the world is in the Lake Superior region, which in 1902 produced 26,977,404 long tons, or 76 per cent of the total output for the United States. No other section of the United States, and no other district in the world, has shown such marvelous development or produced so much iron ore as the region embracing parts of northern Michigan and Wisconsin and the eastern portion of Minnesota. Whether in the same extent of territory elsewhere there may or may not be larger deposits of iron ore of equally desirable composition can not be asserted, for it is by development that these great properties have become known and their reserves approximately determined. But to-day the Lake Superior region stands in a unique position by reason of the large quantity and generally superior character of iron ores won from the five ranges or subdistricts which it embraces. Some of these mines have been in operation for fifty years, a number of them for half that time, but the largest annual producers are later developments.

The initial shipment of iron ore from the Lake Superior region is credited to the year 1856; the development has advanced almost constantly, and about two-thirds of the total product since 1856 has been taken from its mines in the last ten years.

The production of iron ore in the Lake Superior region in the past decade and the quantity previously shipped are as follows:

Production of Lake Superior iron ore, 1893 to 1902, with previous shipments.

YEAR.	Long tons.
1893	6,594,620
1894	7,682,548
1895	10,268,978
1896	10,566,359
1897	12,205,522
1898	13,779,308
1899	17,802,955
1900	20,564,238
1901	21,445,903
1902	26,977,404
Total for 10 years	147,887,835
Previously shipped	73,440,647
Aggregate	221,328,482

The mines of this region are located at an elevation of from 1,000 to 1,500 feet above Lake Superior, the distance from the lake varying from a few to a hundred miles. The output finds cheap transportation for the rail haul to the lakes, has grades favorable to the traffic, and on the lake shores expensive and well-equipped docks have been constructed at seven different ports, where the ore coming in train loads is received into bins, and delivered from the bins by gravity into the holds of vessels. The vessels take the ore from the shipping docks and carry it through two or more of the Great Lakes to receiving docks where equal facilities for unloading by mechanical appliances have been provided. In this way enormous quantities of ore are handled cheaply and expeditiously.

The Lake Superior region is also unique in that its location is such that ore can be delivered at furnaces, in a populous section of the country, and there meet a cheap fuel supply; in other words, its market facilities are unexcelled. It has been this which has chiefly encouraged the phenomenal development.

The quantities of iron ore obtained from the five ranges embraced in the Lake Superior region, taking these in the order of their initial shipment, are as follows:

The Marquette range, in the northern peninsula of Michigan, has contributed since 1854 a total of 66,915,217 long tons, or 30 per cent of the entire production of the Lake Superior region.

The Menominee range, south of the Marquette range and extending from the northern peninsula of Michigan across into northern Wisconsin, has shipped, since 1877, 42,406,228 long tons, or 19 per cent of the entire production.

The Gogebic range, west of the Menominee and Marquette, partly in the northern peninsula of Michigan and partly in Wisconsin, has supplied, since 1884, 38,288,761 long tons, or 17 per cent of the entire production.

The Vermilion range, in the eastern portion of the

state of Minnesota, has, since 1884, sent forward 19,074,424 long tons, or 9 per cent of the entire production.

The Mesabi range, in Minnesota, south of the Vermilion range, in the brief interval since its opening in 1892, has furnished 54,641,532 tons, or 25 per cent of the entire production of the region.

The total production of these five ranges since their opening is 221,326,162 tons, and adding 2,320 tons not credited to any particular range, the grand total for the Lake Superior region is 221,328,482 tons. This far exceeds the quantity of iron ore won from any other mining district in the world, and the amount obtained in the year 1902 from these five ranges, which represents their maximum production, is in excess of the entire production in one year of any foreign country. The quantity of ore won from the state of Minnesota in 1902 has only been exceeded by the yearly production of Great Britain in thirteen years and of Germany in six years. None of the other foreign countries has as yet reached a total approximating this state's 1902 output.

The Vermilion range, in Minnesota, was opened in the year 1884. The ore which is there produced is a hard specular, high in iron, and usually of Bessemer grade. This range is the farthest removed from the principal pig iron producing centers, and the high esteem in which the ore is held is shown by the fact that much of it traverses a distance of over 1,000 miles to points of consumption. The two principal producing mines in this range are known as the Pioneer and the Chandler. Plate I is a surface view of these mines, showing the shafts and various buildings connected with the mining operations, the large open cut, and the extent to which timber has been denuded for mine supports and fuel.

Plate II shows the Auburn mine, on the Mesabi range, in Minnesota. The ore in this deposit is won by the "milling" system, in which the surface earth is removed and the ore drawn through "raises" into drifts located some distance below the top of the ore, making in this way large sinks or craters. This system requires that the cover be stripped, and is especially adapted to shallow deposits of soft ore. The plate gives an excellent view of the crater which is formed by the mining. A steam shovel is at work loading ore cars, which are taken through the tunnel shown to the shaft, through which it is elevated to the surface.

Plate III is a view of the No. 2 pit of the Adams mine, where red hematite is obtained; it is located at Eveleth, Minn. The incline plane is shown bottomed in ore, while in the left of the illustration are seen the tunnels which are run back in the ore. Operations have been carried on at this mine both in open pits and underground.

In some of the newer mines modern apparatus has been installed. Plate IV shows a view of a steel shaft frame at the Adams mine. It is provided with hoppers in which to receive ore from skip cars, and was one of the first of this class to be erected in the country.

Plate V, a view on the Mesabi range, in Minnesota, shows large deposits of ore. These are usually of a comparatively soft character, lying in nearly horizontal strata and with covering of such slight depth that they can be easily stripped. The ore is won by means of steam shovels which place it directly on iron ore cars, in which it is hauled to the docks. In this way immense quantities of ore are cheaply and easily obtained. It is owing principally to these mines that Minnesota shows a larger production per employee than any of the other states.

The view presented herewith shows the Mountain Iron mine, located at Mountain Iron, Minn., in which three steam shovels are shown, one being at work, as seen at the top of the picture, stripping the ore, while in the foreground another shovel is engaged in loading the cars, and on the right-hand side a third shovel is at work.

Around some of the more important mines in the Lake Superior region towns have sprung up, which are dependent entirely upon the iron ore industry. Plate VI shows a group of mine buildings, crusher house, A and B shafts, and some of the dwelling houses located at the Cliffs Shaft mine on Lake Bancroft, Mich., and gives a good idea of the general surface appearance of a well conducted Lake Superior iron ore mine.

The earliest mining in the Lake Superior district was on the Marquette range and one of the oldest operations is the Cleveland mine, which has been supplying ore constantly for a period of over fifty years. Plate VII shows a general view of the Cleveland Lake mine of the Cleveland Cliffs Company, looking from the east. The shaft houses, ore piles, and dumps are shown, together with the ore cars. In the foreground are immense piles of lumber. The lake bed, drained for the purpose of extending mining operations, may also be seen.

Most of the iron ore won in Michigan is taken from underground mines; the only views obtainable of these are such as are taken by flash light. Plate VIII illustrates the Cliffs Shaft mine, one of the more prominent on the Marquette range in Michigan. A mine car running along a track placed at the bottom of the drift is loaded with ore which has been broken down by means of explosives. A power drill in operation is shown in the right of the picture.

Plate IX is a view of part of the open cut of the Salisbury red hematite mine, on the Marquette range, in Michigan.

In the summer of 1903 the Lake Superior Iron Mining Company, a pioneer of the region, celebrated the fiftieth year of its activity, and the following statement,

PLATE VIII.—CLIFFS SHAFT MINE, MARQUETTE RANGE, MICHIGAN.

which embraces the salient points of a contribution for the occasion by the author of this report, emphasizes the development referred to:

Neither the records of the production of the Lake Superior region nor the annual reports of the American Iron and Steel Association go back beyond 1854; therefore no data earlier than this will be exact.

In 1854 there was one mine reported as operating in the Marquette range, the shipments amounting to 3,000 tons. In 1902 the shipments of the Marquette range were 3,868,025 tons, the lake shipments from all ranges in that year reaching a total of 27,039,169 tons.

The production or consumption of iron ore in the United States in 1854 can only be estimated from the quantity of pig iron made. According to the census statistics of 1850 there would have been in the neighborhood of 1,500,000 tons of iron ore consumed during that year, for there was made in the country 563,775 tons of pig iron. In 1854, according to the reports of the American Iron and Steel Association, 736,218 net tons, equivalent to 657,337 gross tons, of pig iron required about 1,750,000 tons of iron ore, whereas in 1902 the country produced 17,821,307 gross tons of pig iron, and the domestic output of all the iron ore mines in the country for 1902 was 35,567,410 long tons.

At least 137 producing mines are now active in the Lake Superior region, a number having exceeded annual outputs of 1,000,000 tons, and one mine has approximated 2,000,000 tons in a year. The estimated iron ore production of the country in 1854 approximated 1,750,000 tons, based upon the reported pig iron production, and the yield of ores did not exceed an average of 40 per cent of metallic iron. Therefore, it is doubtful if in 1854 the United States produced as much iron ore as the Fayal mine in Minnesota did in 1902, which in that year shipped 1,919,172 tons. Considered on the basis of metallic contents, however, this output of the Fayal mine probably produced as much pig iron as was made in the United States in any year up to 1866.

In order to indicate the chemical composition of the iron ores obtained from the Lake Superior district the following statements have been prepared. The first shows what may be considered as representative compositions of standard ores of each of the ranges; and in the second the analyses are for the lower grade ores, which are employed largely because of high silica and low phosphorous contents. These analyses are of ores in their natural condition, and represent cargo lots. Determinations of ores obtained from individual mines in each of the ranges will vary from those given in the statements.

Typical analyses of Lake Superior iron ores.

Alabama-Tennessee, or Southern district.—Next to the Lake Superior district in order of present importance, basing such importance on the quantity of iron ore produced, is the district of which Birmingham, Ala., may be considered the business center, embracing northern Alabama, part of northern Georgia, and part of southern Tennessee. In 1902 Alabama supplied 3,574,474 tons, Georgia 330,554 tons, and Tennessee 874,542 tons, making a total for this district of 4,779,570 tons of iron ore. The bulk of the Alabama ores are red hematites, these ores being largely mined convenient to Birmingham. There is, however, a considerable quantity of brown hematite mined in Alabama and also in Georgia and Tennessee. A statement covering the classification of ores in these three states for the year 1902 may be summarized as follows:

Production of iron ores, Southern district, by states and varieties: 1902.

STATE.	Total (long tons).	Red hematite (long tons).	Brown hematite (long tons).
Southern district	4,779,570	3,054,090	1,725,480
Alabama	3,574,474	2,565,635	1,008,839
Georgia	330,554	117,812	212,742
Tennessee	874,542	370,643	503,899

Apparently the largest development of the hematite ores flanking the Allegheny mountains exists in Alabama, where the red hematite (known locally as Red mountain ores), obtained in large quantities close to deposits of coal suitable for the manufacture of coke, have encouraged the growth of the iron industry. The red hematites are locally recognized as soft and hard ores, the former, being at or near the surface, are partially decomposed; the latter are mined by underground workings and may be subdivided into siliceous ores, in which silica is present in quantity, and "limey" ores, in which the proportion of lime may be such as to make the ore approximately self-fluxing. Nearly parallel with the Red mountain deposits are important beds of brown hematite and limonite ore, occurring in isolated deposits, some of large extent. In fact, the exploited brown hematite deposits of this region are of greater average extent than those found in other portions of the country. Occasional deposits of magnetite are also found in the Alabama-Tennessee district, but few have been worked. Some carbonate ore has also been won and used in the manufacture of special irons.

Plate X illustrates the openings at one of the Red mountain mines near Birmingham. Plate XI is a view of a limonite bank near Tecumseh, Cherokee county, Ala.; the ore is broken down, loaded onto tram cars, as shown, and taken to washers, from which it goes to the railroad cars.

New York and New England.—Magnetite iron ores are produced chiefly in New York, New Jersey, and Pennsylvania, but some are won from North Carolina, Michigan, New Mexico, and Utah. The deposits of

this class of mineral in New York state are phenomenally large, and so far as metallic contents are concerned, unusually rich; but many carry phosphorus, sulphur, or titanium in excess, some of the most extensive deposits having so much titanium that they have not been brought into commercial use. High phosphorous ores, however, have been and are mined to a large extent, and beneficiated by magnetic concentration. Some ores in the vicinity of Port Henry, N. Y., carry as high as 3 per cent of phosphorus, as apatite, mixed with the magnetic crystals, which, after the ore is comminuted, can be readily separated, either by magnetic separators or by jigs. Other ores of the Port Henry mines district are of Bessemer grade, and from one opening 30,000 tons of very high grade magnetic ore were obtained. This ore approached chemical purity, was of Bessemer grade as to phosphorus contents, and was practically a mass of well-defined octahedral crystalline forms, some an inch and a quarter on the face, many having practically perfect proportions. Still larger sized crystals have been found, but these were more or less imperfect, and masses of crystals affected by pressure had some faces flattened.

The localities which have been worked in the Lake Champlain district are the mines at Chateaugay, west of Plattsburg; the mines at Moriah, west of Port Henry; and those west of Crown Point. These deposits are at elevations of from 600 to 1,000 feet above the level of Lake Champlain, and while some explorations originally developed beds of considerable size by an open cut, most of the mining is now underground, and much of it at a depth of 500 feet or more. Some mines which have been exploited are adjacent to the shore of the lake, others are close to the Adirondack mountains, and some are on the western side of the range. Prominent among the titaniferous ore deposits are the Split Rock mine, on Lake Champlain, and the Adirondack Village mine, close to the main Adirondack range. These titaniferous ores were utilized in former years by the Catalan or direct process, in which the ore was converted into metal by charcoal in open hearths.

The Port Henry mines, located at Mineville, near Lake Champlain, in Essex county, have long been famous as a source of iron ore supply; it is claimed that the first ore was taken out in 1804. The ore is a dense magnetite, and Plate XII is a view of No. 21 mine of the Port Henry Iron Ore Company. It shows the large pillars of pure ore left to support the roof of the mine, the operations now being practically all underground. It is estimated that there are in the pillars of this mine and of the mines adjoining, belonging to Witherbee, Sherman & Co., at least 800,000 tons of ore. The deposit is very large, having a thickness in some places of 400 feet. The ore bodies are divided into two parts by a horse of rock, and at the lower depth diamond drillings have indicated the existence of two underlying veins of ore high in iron and phosphorus and low in silica. The ore which is sold in the market is high in iron, but also contains phosphorus in the form of apatite, making it all of non-Bessemer quality.

Other deposits of magnetite occur in the Hudson river district, the most pronounced exposures and veins being south of West Point on the Highlands east of the Hudson river, extending as far as Croton Falls, but some magnetite is also found west of the river, and this line of deposits can be traced from New York into New Jersey. The southern New York magnetites are, as a rule, lean, and contain either an excess of phosphorus or, more frequently, of sulphur. There has been considerable exploitation of these deposits, but outside of the Tilly Foster mine none has been a large producer, and all are inactive. The Tilly Foster appeared to be a large lens, which was worked first as an open bed, then the ore body was followed by shafting, the rooms being filled with concrete arches to permit the removal of pillars, and finally the working was restored to an open pit by the removal of 600,000 cubic yards of overlying rock. Large expenditures were also made on the Theall mine, near Brewster, which was worked by an extensive tunnel with stopes, shafts, and galleries. A concentrating plant was erected at this mine, but subsequently dismantled. The Benson mine in northern New York, west of the Adirondack mountains, has also installed a separating plant, and has produced merchantable concentrates in considerable quantity from lean magnetites. The Lake Champlain district has been prominent in the efforts to beneficiate ores by concentration by the use of jigs, and also by magnetic separators. At the Port Henry mines is the largest separator plant in the country.

New York is one of the few states where, in addition to the magnetites, the three other varieties of iron ore are found. Red hematite is mined from the north central portion of the state, in Jefferson, Clinton, and Oneida counties; brown hematites are won in the southern portion, east of the Hudson river, in Dutchess and Columbia counties, and in the same district carbonate ore has been found to a considerable extent, and a large plant for roasting these ores has been constructed near Catskill Landing.

Some of the brown hematite mines along the Harlem Railroad have been worked for many years, and have been, and are still, the main reliance of the charcoal iron industry along the Connecticut and New York boundary. This same class of ores extends into Litchfield county, Conn., and Berkshire county, Mass., the district being generally recognized as the Salisbury region. The rapid denudation of available timber, and the necessity of operating small blast furnace plants producing a special grade of pig iron, has reduced the number of furnaces, so that now only a few are making iron with charcoal; these smelt brown hematite and some carbonate ores.

In addition to the brown hematite ores mentioned as

PLATE IX.—THE SALISBURY MINE, MARQUETTE RANGE, MICHIGAN.

occurring in southwestern Massachusetts and northwestern Connecticut, bog ores are found in eastern Massachusetts, and were the foundation upon which the first practical development of the iron industry in the United States was based. Magnetic ore occurs in Rhode Island, and magnetites and brown hematites have been mined in Maine and Vermont.

New Jersey.—The magnetite ores extending from New York across northern New Jersey into Pennsylvania, have been liberally developed in a number of locations in New Jersey. The importance of the industry, however, has declined in late years, the bulk of the product being confined to a few of the more important mines. As a rule, the ores of New Jersey are lean, and some of them carry sulphur or phosphorus in excess, but others are of Bessemer grade. In western New Jersey magnetites also occur in a decomposed condition, and carry considerable manganese. Brown hematites are found in western New Jersey, in the vicinity of Belvidere, but have not been extensively developed. The early iron industry of New Jersey was based upon the use of bog ores, which came from the district close to the ocean front; these are no longer used, and all of the ore won in New Jersey is of the magnetite class. The beneficiation of magnetic ores by washing and by separation has reached a development in New Jersey approximating that of the state of New York. The failure of some of the more pretentious magnetic separating plants, which comminuted ore finely, has encouraged magnetic cobbing and the treatment of ore as coarse grains by separators. The roasting of dense ores is also a feature of New Jersey blast furnace practice.

Pennsylvania.—Pennsylvania, although not the pioneer in American iron industry (its initial enterprise having been established about 1716), rapidly advanced to first place, and by reason of the wide distribution of all classes of iron ore and abundance of fuel, became the largest producer of iron, and still holds that rank, although the bulk of the iron ore used in the manufacture of its iron and steel products is mined outside of the state.

The most important iron mining operation in Pennsylvania is that carried on in the Cornwall ore deposit in Lebanon county, which has produced about three-fourths of a million tons annually, and, since the year 1740, has contributed a total approximating eighteen million tons to supply Pennsylvania iron works. This ore as mined yields on the average about 46 per cent of iron, carries about three-fourths of 1 per cent of copper, and about 2½ per cent of sulphur. It must, therefore, be roasted, and ore-roasting kilns have here obtained their largest development. Furnaces of the Gjers cylindrical form, using solid fuel, are used at some plants, and at others there are circular or rectangular kilns heated by producer gas after the Davis-Colby patents.

The Cornwall ore bank, at Cornwall, Lebanon county, is a large deposit of magnetite from which immense quantities of ore have been won. Most of the ore is obtained above water level, cars being run in on a series of terraces. The ore is broken down and loaded onto cars by means of barrows, and thus transported to the furnaces.

Plate XIII shows two terraces in solid ore, with the workmen engaged in filling the ore cars. In the background of the picture a stripping which covers the ore can be seen.

Along the South mountain, from the Delaware river to and beyond the Susquehanna river, deposits of magnetic iron ores are found and have been worked. In Lehigh and Lancaster counties at present they are mined chiefly for concentration, as the ore is lean. In Berks county a large underground development was made at Boyertown, some shafts extending over 600 feet in depth, the ore being, as a rule, low in phosphorus but high in sulphur, and requiring roasting. These mines are being unwatered to make it possible to obtain ore. Between Boyertown and Cornwall a number of magnetic deposits have been worked spasmodically, and beyond the Susquehanna, in Adams and York counties, similar mines have been in operation. In Lancaster county a magnetic concentrating plant has lately been installed, operating on a large mass of lean magnetite, which is crushed, sized, and separated, the object being to form the concentrates into briquettes for use in blast furnaces.

Along the northern and western faces of the South mountain, and in the valley between the South and North mountain ranges, brown hematite ore has been mined in many localities, some of the deposits having been worked on a liberal scale, and others, producing but little, have a history approximating a century of time. As a rule, these brown hematites require washing to make them desirable for blast furnace purposes, and they yield, after such treatment, about 45 per cent of iron, some with 2 to 5 per cent of manganese, and all with phosphorus above the Bessemer limit. Other brown hematites of nearly similar composition occur in central Pennsylvania, along the eastern flank of the foothills of the Allegheny mountains, in Bedford, Center, Huntingdon, and other counties. In the same region fossil and red hematites are won by underground operations, and this is true also of deposits in northeastern Pennsylvania, along the Blue mountain range, and in the vicinity of Danville and Bloomsburg. Practically all of the brown hematites have been won from open cut workings, the ore occurring with clay and limestone, and requiring washing. Much of the red hematite was mined from small underground drifts.

In the bituminous coal belt, which extends across Pennsylvania from northeast to southwest, with the Allegheny mountains as an axis, the carbonate ores obtained were formerly an important base of supply. The location of many of these ores in small veins, the

exploitation of which is expensive, the necessity of roasting them, and their generally high phosphorus content have much limited their use.

Delaware and Maryland.—In Delaware there are several isolated deposits of brown hematite which have been worked but are now inactive. In eastern Maryland carbonates which occur mixed with clay are mined in a desultory way by farmers and used near the city of Washington to produce a special grade of pig metal with charcoal. In western Maryland there are brown hematites in considerable quantities, also indications of red hematites, and some lean magnetites, which, while appearing to occur in large proportions, would have to be concentrated to be merchantable.

The Virginias and Carolinas.—In Virginia the bulk of the iron ores mined are of the brown hematite class, some occurring in beds of clay, others in a form approaching veins embedded in rock strata. Minor deposits of red hematite also exist, and in southwestern Virginia and in western North Carolina there are large bodies of magnetites. Titaniferous magnetites and brown hematites occur in central North Carolina and extend into South Carolina, Georgia, Tennessee, and Alabama.

The Appalachian mountain chain is bordered by iron ore deposits from northern New York through New Jersey, Pennsylvania, Maryland, the Virginias, North Carolina, Tennessee, Georgia, and Alabama. These deposits are mostly magnetites and brown hematites, the latter generally showing in the valleys, the former often in foothills or on the slopes of the mountains. Some red hematites are also found on the mountain slopes. Nearly paralleling the Appalachian range, and occupying positions in the foothills of the Allegheny mountains, are deposits of brown hematite, also of carbonates. The carbonates are more abundant in the coal bearing regions, and occur on both flanks of the Allegheny mountains.

Still farther west carbonate ores and some brown hematites are found in the coal measures of western Pennsylvania, West Virginia, Ohio, Kentucky, and eastern Tennessee; red and brown hematite are abundant in Kentucky and Tennessee.

Ohio.—The ores obtained from Ohio and from the portion of Kentucky adjacent to the Ohio river are either carbonates or hematites, resulting from the weathering of carbonates; these have sustained a considerable iron industry for many years in southern Ohio and in Kentucky, in a locality known as the Hanging Rock region, with Ironton, Ohio, and Ashland, Ky., as business centers. The original installations were all charcoal furnaces, some of which are still active; for a time some furnaces used raw bituminous coal, but the larger plants are now dependent on coke, local ores being used, supplemented by other ores from the Lake Superior region.

There are also in Kentucky excellent deposits of limonite, and these extend into Tennessee, some quite important mines existing in the central and western portions of the state. There are also carbonates in the southwestern section which extend into Mississippi. Carbonate ore also exists in northern Florida.

Wisconsin and Iowa.—The liberal exploitation of the iron ores in the Lake Superior region has directed attention to deposits in adjacent states. In central Wisconsin brown hematite exists in pockets or lenses. In southern Wisconsin there is a unique deposit of high phosphorus red hematite ore, which, owing to its physical structure, is known as flaxseed ore, and an apparently large quantity of red hematite of excellent composition has also lately been discovered by drilling and shafting in the vicinity of North Freedom, Sauk county, Wis. This deposit is expected to be a factor in the iron ore supply of Chicago and vicinity. In northeastern Iowa brown hematites have been wrought, and carbonates are found in the western section of the state.

Missouri and Arkansas.—Missouri attained prominence as an iron producing state several decades ago through the Iron Mountain and Pilot Knob deposits, which gave promise of being large producers, but as development proceeded these ore beds were practically exhausted, although it is possible there may be undiscovered extensions of them. In central, eastern, and southern Missouri red hematite and brown hematite ores are obtained in quantities, and these ores also extend into Arkansas, although there has been no development in that state.

Texas.—The exploitations for iron ore in Texas have been chiefly in the northeastern section, where brown hematites have been won from near the surface, and the fact that these lie in nearly horizontal layers, covered but slightly with a ferruginous sandstone and sand, suggests that they are bog ores forming the bottom of an extinct lake. They extend over a large territory, except where the plateaus are cut by water courses. In central Texas an important deposit of red hematite ore, claimed to be of excellent quality, has been opened up, but in the absence of demand for this mineral exploitation has not been prosecuted.

Rocky Mountain region.—The section of the country which may be considered as the Rocky Mountain region has a number of important deposits of iron ores and all the general classes of ores are found. In what might be called the distinctively mountainous section, on the western slopes, magnetites are obtained, and some deposits of apparent magnitude are known to exist, but owing to the high elevation of the deposits and the amount of snow encountered, they have not been exploited. It is possible that the increasing demand for iron ores may encourage development.

The iron ore deposits at Sunrise, Laramie county, Wyo., are quite extensive; until late years, however, but little ore had been produced from them. The ore is a red hematite occurring in carboniferous lime-

PLATE X.—RED HEMATITE MINE, RED MOUNTAIN, NEAR BIRMINGHAM, ALABAMA.

PLATE XI.—LIMONITE BANKS NEAR TECUMSEH, CHEROKEE COUNTY, ALABAMA.

stone; covers, as it is claimed, a superficial area of about 20 square miles; contains from 60 to 67 per cent of iron from 2.5 to 5 per cent of silica, and is low in phosphorus. It is won by open cut working, as shown in the illustration, the steam shovels loading onto cars on which it is taken to the furnaces at Pueblo, Colo. The view (Plate XIV) shows the ore *in situ* together with the covering of limestone and earth.

In New Mexico there is a deposit where red hematite and magnetite ores are obtained. The Fierro, or Union Hill, and Jim Fair mines are located in the territory of New Mexico, near Hanover. Mr. D. M. Barringer, M. E., states that the ore generally, but not always, occurs with eruptive granite and limestone, probably carboniferous, the vein being vertical or dipping at a steep angle. The ore of the Union Hill mine is a mixture of approximately 75 per cent magnetite and 25 per cent hematite, and is quite hard.

The ore of the Jim Fair mine is of practically the reverse composition to that of the Union Hill, the greater portion being of the hematite variety, and is also quite hard. Both here and at the Union Hill mine the ore stands in dikes, and is quarried out in open cuts. Mr. Barringer states that at one place there is a large deposit of brown hematite ore, and at one point there is also a considerable amount of specular ore. The ore carries satisfactory percentages of iron, and is of Bessemer quality. The permanency of this deposit does not seem assured from the results of mining operations to date.

In the San Luis valley of Colorado, which may be said to be in the heart of the Rocky mountains, brown hematite ores are mined, and one mine has been phenomenal not only for the quantity taken from it, but also for the low percentage of phosphorus in the ore. In fact, the product has been persistently a Bessemer ore, and it is probable that no other deposit of brown hematite has produced as much low phosphorus ore as the Orient mine. This mine is located in the eastern part of Saguache county, Colo., about eight miles from Villa Grove, and was opened in 1882. The ore body is from 30 to 150 feet in width and is worked by means of tunnels, from which stopes are run. Over 1,000,000 tons of ore have been obtained from this deposit, but unfortunately it shows signs of exhaustion. It may be, however, that deposits of similar character will be found in the same district.

Plate XV is a view of the Orient mine, showing one of the inclines from which the ore is loaded onto cars for transportation to the blast furnace.

Between the Pacific coast and the Rocky mountains there are a number of deposits of iron ore, but few have been exploited, because there has been little or no market for the mineral. Blast furnaces which were located at Ogden, Utah, at Clipper Gap, Cal., and at Salem, Oreg., have ceased operations, and the only enterprise now active is near Port Townsend, on Puget sound, in the state of Washington. This plant has drawn its supply in part from local hematites (bog ores), but is largely dependent upon magnetic ores imported from British Columbia. The plants now idle relied, when in operation, mostly on brown hematite ores mined near the furnaces, with the exception of the plant in Utah which received as part of its supply red hematites from Wyoming. In northern and southern California magnetites and red hematites are reported, but nothing beyond exploratory work has been done upon them. When satisfactory supplies of metallurgical fuel become available it is possible that some of these Pacific coast deposits may be exploited. Magnetite has also been mined near Lovelocks, Nevada.

VALUE OF IRON ORE DEPOSITS.

The determination of the value of iron ore deposits is difficult, for they are only serviceable in so far as the material of which they are composed may be utilized. Thus, a mountain of excellent iron ore remote from blast furnaces or other means of utilization, without transportation facilities to carry the mineral to points where markets exist, would stand practically useless until these conditions were modified.

The quality of the iron ore obtainable has a decided influence upon the value of the product, and therefore upon that of the deposit. Ores low in phosphorus, although with moderate iron content, command premiums over those carrying this element in excess, and in the present state of metallurgical development ores carrying titanium are considered undesirable, although in the near future they may possibly be sought after. A sulphurous ore requiring roasting is less desirable than one free from sulphur, and ores which require washing or beneficiating, either by jigs or magnetic separators, have less value than those which can be used in their native state. Therefore, the apparent quantity and average quality of an ore in a deposit and its accessibility to markets or prospective points of consumption affect its value. Where a mine is producing and where the tests made to determine the apparent extent of the deposit are satisfactory, its value may be gauged by capitalization based upon a royalty charge for ore mined, for in an ore deposit the material taken out is not reproduced, and therefore some allowance covering a value for the ore won is proper.

The difficulties of determining the value of iron ore deposits are increased by the fact that in some instances mere mining rights are granted, while in others a proprietor may allow a mining company to take ore at a fixed rate per ton, or upon a sliding scale. In still other cases the ownership is in a state which grants mining leases at tonnage rates; these leased properties after having been explored or developed are sublet, and thus two or more royalties may be cumulative. A deposit of ore has no definite value to the lessee or sublessee, other than what he gets out of it during the

term of his lease, for he has no interest in its future and the owner can practically base no estimate of value except by capitalizing its earning capacity, providing that earning capacity can be maintained. Another feature which has caused trouble in an attempt to determine approximate valuations for the iron ore deposits of the United States has been that a company may own or lease a considerable tract of land only a small part of which has been explored or exploited. It would be manifestly unfair to base an estimate of the value of the entire property upon results obtained from a limited area.

During July, 1902, an interesting suit in chancery developed the estimate which the officers of the United States Steel Corporation placed upon its iron ore properties. Practically this estimate claimed that the corporation had in reserve, in deposits which had been tested, over 700,000,000 tons of iron ore, upon which the company placed a value to itself of $1 per ton. This was not merely a royalty estimate, but represented what the officers of the corporation considered the ore was worth as a material for conversion into merchantable products, taking into consideration the location of the deposits in relation to its furnaces and mills, and the fact that as far as known this supply could not be duplicated elsewhere, certainly not within any limit of transportation to the corporation's existing plants. This valuation was questioned because an official of the corporation had stated that it had reserves of ore and fuel sufficient for sixty years, the assumption being that the value of a supply of mineral which would not be exhausted before sixty years would be strongly affected by the interest which the money invested should earn in that time. In a case such as indicated, an iron ore deposit which produces a quantity of ore desirable in quality, so as to be of material service to the industry, undoubtedly possesses a value to the owners which is not fully measured by a mere royalty charge, for it acts as a basis for supplying raw material and gives the owner not only a possible profit on the mining, but a protection in cases of fluctuations in prices of ore, a value difficult to estimate in money.

COMMERCIAL VALUE OF THE PRODUCT.

The determination of the value of iron ores is contingent upon the character of each ore, its chemical components, its texture, its location in relation to blast furnaces where it can be used, and transportation facilities. The custom heretofore followed in census reports of ascertaining as closely as possible what commercial value the various ores represent at the mines, including any royalty or allowance for royalty, and excluding all transportation charges has been followed in this report. In discussing the output by states, the value of the ore delivered at points of consumption is not taken into consideration, but comparisons are based upon what the ores are commercially worth at the mine ready for market. The value, however, should and does include the cost of beneficiating ores when they receive such treatment, so as to make the record show the total value of the iron ore produced in each state.

The prices of the Lake Superior ores of Bessemer quality are based on a standard ore yielding 63 per cent of iron when dried at 212° F., with 0.045 per cent phosphorus and 10 per cent moisture, equivalent to 56.7 per cent of metallic iron in the natural condition. The standard for non-Bessemer ores yields 60 per cent of iron when dried at 212° F., with 12 per cent moisture, equivalent to 52.8 per cent metallic iron in the natural condition. The calculation to determine the selling price is made on ores having the above hypothetical analysis, delivered f. o. b. cars at blast furnaces. If the ores yield above or below the chemical standard the price is adjusted accordingly by premium or discount. The scale for Bessemer ores takes into account the percentage of both iron and phosphorus. The price of non-Bessemer ores is determined in the same way, but usually only metallic iron is taken into consideration unless other constituents are excessive.

The physical condition of iron ores—that is, whether they are coarse or fine, dense or open in structure—also affects their commercial value. The Mesabi range ores are divided into three classes, according to their degrees of fineness, as determined by sieve tests; the second class is 10 cents, and the third class 25 cents below the price placed upon the first class.

All of the ore mined in the United States is not utilized in the production of metal for steel manufacture, for in this freedom from phosphorus is generally necessary; an excess of this element, however, is admissible in iron treated by the basic Bessemer process.

For use in foundries, for treatment in puddling furnaces, and for other purposes which, taken together, consume approximately one-quarter of the pig iron produced, the limitations as to phosphorus are less rigid. For these purposes many ores may be smelted which are not considered desirable in manufacturing pig iron for conversion into steel. However, other elements than phosphorus demand consideration, and in the selection of ores their chemical composition determines their availability for specific use. The percentage of iron which an ore yields is the first consideration, for upon this the economy of smelting primarily depends, but objectionable elements or oxides may encourage the selection of an ore containing less metallic iron, but freer from objectionable constituents than an ore with high iron contents associated with deleterious ingredients.

Seeking for large outputs of metal of a particular composition, and for low fuel consumption, blast furnace managers may refuse nearby ores lean in iron or carrying undesirable constituents, and bring from a

PLATE XII.—VIEW OF NO. 21 MINE, PORT HENRY IRON COMPANY, MINEVILLE, NEAR PORT HENRY, NEW YORK.

distance ores with larger percentages of metal or with very little of phosphorus, sulphur, titanium, etc.

The following table shows the quantity of iron ore produced in each state and territory in the United States, its value, and the average value per ton, for each year from 1899 to 1902:

TABLE 13.—QUANTITY, VALUE, AND AVERAGE VALUE PER TON OF IRON ORE, BY STATES AND TERRITORIES: 1899 TO 1902.

STATE OR TERRITORY.	1902			1901			1900			1899

[1] Includes South Carolina.
[2] Includes Montana. No product reported for Nevada.
[3] Includes Texas and Montana.
[4] Includes Montana.
[5] Includes Iowa.
[6] Includes Vermont.
[7] Included with Nevada, New Mexico, Utah, and Wyoming.

The values at different mines vary greatly and only the averages are presented in the above table. In considering these values it must be remembered that they represent the labor employed and the expenses of operating, royalties, or sinking fund, but no transportation charges. These values are not the selling prices of the ores, which are gauged when delivered either at the furnace or at receiving points where they are handled for distribution.

MINING METHODS.

Iron ore deposits in the United States vary materially in character, size, and occurrence, and the geological and physical conditions of the several varieties generally known as magnetite, red hematite, brown hematite, and carbonate ores require different methods of exploitation which also vary greatly. The known character, the apparent dimensions, the general form, and the position of an iron ore deposit, with reference to the surface and water, the physical structure or chemical composition of the material to be extracted, the character of the earth or rock inclosing or occurring in the ore body, the stratification, dip, and strike, the simplicity or complexity of the ore body, the convenience of the deposit to an available market for its product, and the capital at command of those who attempt the exploitation all influence the methods followed in mining iron ore.

Where the ore body projects above or lies close to the surface, or where in a large apparently well defined deposit the cover can be stripped to advantage, the exploitation may be carried on by open cut work, from which the ore is taken out either by train or, after digging, lifted by steampower applied to inclines or to vertical hoists.

In the Mesabi range of Minnesota, in the Sunrise district of Wyoming, and in a number of brown hematite deposits of the South, large open cuts are worked by the use of the steam shovel, these appliances removing the ore in successive benches after large areas have been stripped by the same method.

Where the body of ore is under considerable cover, if the roof is firm, or if the vein matter is comparatively narrow and the dip steep, it is removed through shafts, either vertical or inclined, and through tunnels or adits. In a number of instances open cut work has, after reaching a considerable depth, been supplemented by underground exploitation, while in a few cases this method has been reversed and a large open cut has supplanted underground work. The shafts or adits, which are generally expected to serve as long as the deposit yields ore, are necessarily costly and need to be planned and located with care, for through these the miners have access to the underground workings, and the ore and water are carried to the natural surface.

Except when the strata penetrated are exceptionally compact and hard, the shafts or adits must be substantially timbered, so that they can be maintained until the deposit is exhausted; they are excavated either in the ore or in inclosing rock, and if in the ore large

bodies are left adjacent to these avenues of approach as a safeguard against accident. From these main arteries drifts are opened either parallel or at different angles in wide or shallow deposits, or at determined depths in narrow and deep deposits, and from these in turn supplementary drifts are run and rooms or stopes excavated.

In deposits dipping considerably from the horizon one prevailing method of exploitation is to open a series of drifts at different levels, from which mining is carried on simultaneously; the upper levels are farther advanced than those below, the ore being taken out in horizontal sections or slices, known in mining parlance as stopes. When the ore is worked above a given level and allowed to fall by gravity, through chutes or otherwise, to vehicles which deliver it to the main arteries, the method is called "overhand stoping." Where the material is attacked below a level and the ore raised to this level, the method is recognized as "underhand stoping." The overhand system is, under most circumstances, the cheaper and more advantageous, but the underhand stoping is necessary in taking up floors, removing pillars, and in some open cut work.

In underground operations the space made void as the ore is removed must be protected, at least in part, either by timbering or by filling in rock or other waste material. In some instances the ore, if hard and if left in pillars alternating with rooms or stopes, will safely support the roof, but often the proportion of ore sacrificed is too great to make this method desirable.

After shafts or adits have been sunk and main drifts run the ore is taken out by various systems, which may be briefly designated as follows:

"Milling," in which the surface earth is removed and the ore drawn through "raises" into drifts located some distance below the top of the ore, thus making large sinks or craters. This system requires that the cover be stripped, and is especially adapted to moderately shallow deposits of soft ore covering a large area.

In "caving" a series of levels connecting with the main shaft or with several shafts are simultaneously worked, the ore being taken out from the upper levels and delivered through winzes to lower levels which are protected by the ore *in situ*. As the ore is removed from the portion of one level the superincumbent rock or earth is allowed to cave upon the ore below, and frequently the settling of the material is facilitated by the use of explosives. By this method but little ore need be left in a deposit, and if care is exercised the risks are not great and but little waste becomes mixed with the ore. This method is applied more to soft or moderately soft ores than to those which are harder, but it is used in some hard ore mines where the roof or hanging wall is insecure.

"Drifting" is employed in all underground mining, but where a series of parallel drifts, one advanced more than another, are employed to slice off the deposit the method is specifically known as the "drifting or slicing system."

"Room mining" may be considered either as digging out cavities which alternate with pillars, or as opening cavities of considerable length, width, and height, usually from foot wall to hanging wall, and supporting the last named and the roof by an elaborate arrangement of timbers known as square sets, in which the timbers are so placed as to form the outlines of a series of cubes resting upon one another by carefully fitted joints. This method is largely employed in removing soft hematite, and some of the cavities thus made and protected are of enormous size.

"Filling" is not so much a method of mining as a means of protecting the workings by depositing in the cavities waste rock, sand, and other refuse. This method is often more economical than timber support, and is adapted to hard ore mines.

The magnetites, as a rule, are found in fairly well-defined veins, inclosed between walls and dipping at steep angles from the horizon. Some of these veins are of enormous size, as in the Lake Champlain district of New York, where the texture and hardness of the ore permit of its use as pillars in the mines. Other veins are narrow and tortuous, although persistent, and each of these characteristics demands different methods of exploitation.

Where magnetic iron ore is obtained from underground operations the ore left as pillars generally furnishes sufficient support for the roof. There have been instances where the proportion of the total ore in the deposits which these pillars represented was so large, or the tendency of the mineral to break from the pillars in large masses was so great, as to cause their abandonment.

FINE ORES.

During late years there have been interesting discussions in the technical press concerning disturbances in blast furnaces, which are attributed largely to the increasing use of finely comminuted iron ores. The troubles have been emphasized by the contemporaneous development of the Mesabi range in Minnesota, where a majority of the ores occur finely comminuted, some practically as powder, by the use of concentrated ores, and by the increase in the dimensions and power of blast furnaces. As a result, fine ores have been discredited, and explosions, slips, and losses in the blast furnaces have been attributed to the use of these ores. Fine ore is undoubtedly more troublesome in the blast furnace than ore which is of moderate size, as the comminuted material is liable to sift down through the charge and accumulate in portions of the furnace, increasing the resistance of the blast, and a portion as flocculent material is carried over with the furnace gases. In some blast furnaces the latter represents so large a proportion of the ore charged that the material

PLATE XIV.—SUNRISE PIT FROM THE EAST, AT SUNRISE, LARAMIE COUNTY, WYOMING.

PLATE XV.—NOS. 3 AND 4 TRAMS AND RAILROAD TRACKS, ORIENT MINE, NEAR SALIDA, SAGUACHE COUNTY, COLORADO.

is recovered and formed into briquettes, or made into mud with water, to be returned into the furnace.

There is no intention to question the desirability of using relatively coarse ores in blast furnaces, but it is probable that fine ores are blamed for some disturbances for which they are only partially responsible. The accumulation of fine material of any kind in a portion of a blast furnace may cause unequal settlements, slips, or irregular operation, and, while the fine ore is subject to this, the same results may come from an accumulation of comminuted coke and fluxes. In the enlargement of blast furnaces the system of feeding materials has been radically changed. Where thousands of tons are fed daily into the throat of a blast furnace, the handling of this becomes an important matter, and labor-saving appliances are demanded. A few years ago the general practice of blast furnaces, of what was then large size but would now be considered of moderate dimensions, was to discharge the raw material from cars running upon trestles, shovel or fork this into charging buggies which were elevated to the top of the furnace and discharged upon the bell, which closed the throat by fitting against the hopper. But where large quantities are daily handled bins have been introduced which take the place of trestles, and the material, instead of being shoveled or forked into the discharging buggies, drops from railroad cars into bins and from bins through chutes into scale or weigh cars, thence into skip cars, which are lifted considerably above the top of the furnace and dumped into the receiving hopper, thence through a bell and chamber to the main furnace bell.

Bins have been erected to considerable height, and in dumping the material, particularly coke, into the bins, or in passing it through them, it becomes more or less broken. At some furnaces the coke bin discharges immediately into the skip car running to the top of the furnace, but in a majority of cases the weigh car intervenes. As a consequence, a large percentage of coke is ground to powder, for it may have an aggregate drop of from 30 to 50 feet from the time it leaves the car in which it is transported until it touches the main bell of the furnace.

In the smelting operation there is no opportunity for coke to be consumed until it approaches the tuyeres of the blast furnace, for it is here that the combustion of the fuel is made possible by the admission of heated air. An excess of free oxygen would carry this combustion to a point which would result in imperfect and irregular furnace operation, consequently the fine material which may accumulate in the shaft or upper portion of the furnace may be added to until it is in such volume and position as to cause a disturbance by slipping, resulting in increased pressure of blast, and an irregular working of the blast furnace. While the same may be true of the fine ore, this has the advantage of being reduced by the gases resulting from the combustion of the fuel. Investigations of some of the larger furnaces blown out for repair seldom show unreduced ore, although the proportion of fine ore fed may have been large, but indicate volumes of coke dust adjacent to the walls or accumulated in different portions of the blast furnace. The combination of fine ore and fine coke may therefore be considered largely responsible for many slips and irregularities, but it is possible that explosions which have been so severe at a number of furnaces are attributable primarily to flocculent incandescent carbonaceous matter (resulting from the grinding of the coke), meeting oxygen under conditions similar to those in coal mines, flour mills, and grain elevators.

The quantity and chemical character of the fine ores which are available demonstrate the necessity of their use, and it is the duty of those designing or operating blast furnaces to provide for such utilization, and where satisfactory operation is secured under disadvantage the manager of a plant is entitled to proper credit for overcoming difficulties. The constructor must take into consideration the handling and distribution of this material, and also design and equip the furnace to meet the excessive pressure or unequal settlement which may be traceable to the fine ores, whether associated with fine coke or not. The latter condition will exist to some extent in any furnace, although for the reasons given above the quantity of fine coke is undoubtedly greatly magnified in the recent method of handling the materials. Ores which cost at the furnace 5, 6, or more cents per unit of metal can not be wasted with impunity, and where it is found impracticable to control the loss of fine ore through the gas flues, the collection of these, and their preparation for subsequent treatment, demand attention. The briquetting of fine ores, whether in their natural state or after beneficiation, is also commanding attention. Whenever an iron ore is handled and rehandled, passed through any mechanical apparatus, or heated, there is additional cost placed against it, and this cost will naturally affect the price of pig iron. However, it may be assumed as an axiom that the treatment of ores preliminary to their being fed into the blast furnace can generally be considered as more economical than depending on the furnace to do the work.

Methods of cheaply beneficiating and briquetting fine ores so as to introduce them into the blast furnace, and permit of their being carried down into the zone of reduction before changing form, seem to present a possible feature of advance, to which those interested in the smelting of iron can well afford to give attention.

While fine ores are considered by many managers undesirable, there is also objection to the mineral being of large size, especially in dense magnetites or red hematites. Preliminary crushing to approximately uniform size is therefore desirable, and to meet furnace requirements large crushing plants are in use at

some important mines, the purpose being to reduce the hard ores to sizes convenient for handling and adapted to quick reduction.

CONCENTRATION OF IRON ORES.

In various parts of the country there are deposits of iron ores of considerable magnitude in which the amount of metallic iron is insufficient to justify the mining of the mineral and its use in blast furnaces. Some of these deposits are located so that the ore can be cheaply mined, and are also convenient to transportation facilities to market.

To reduce the percentage of gangue and to produce material carrying iron sufficient for economical smelting, these ores need to be beneficiated, and usually they are comminuted by crushing or grinding if they are not naturally of a size suitable for the purpose. After reduction in size the ore is either passed through jigs, where in connection with water the iron oxide separates from the gangue by specific gravity or the fine material is delivered to magnetic separators. The separation in jigs is effected when the specific gravity of the iron oxide and the gangue differ sufficiently to permit of a good separation. In magnetic separation the magnetic particles are attracted to belts, drums, or to stationary magnets and the gangue or such portion as is feebly magnetic is rejected. In either process time and the degree of comminution are elements in securing satisfactory results. Magnetic separation is confined to the treatment of lean magnetic ores or to hematites which are made magnetic by preliminary roasting, although some of the apparatus used discriminates satisfactorily between minerals of moderately different magnetic quality.

The size of the grains of ore intermixed with the gangue determines the possibility of perfection being approached by either system of concentration. But in many ores these grains are so small that the comminution required adds greatly to the cost, and also produces material whose desirability for smelting purposes is limited. Consequently, most of the concentrating plants do not attempt to attain perfection in separation, but produce a concentrate which, while below the possible standard of purity obtainable, is acceptable to the blast furnace managers because of the size of the grains. It is found to be advantageous to lose a portion of the mineral in the tailings rather than to attempt perfection with the separators. In some cases the tailings, when practically free from iron, are re-treated because of the value of these by-products. The sand resulting from a siliceous ore finds a ready sale, and the apatite separated from high phosphorus magnetite is in demand for fertilizing.

The magnetic separators in use in the United States in 1902 produced 192,285 long tons of commercial ore. Most of this was magnetite ore. In addition a cobbing method was used, wherein ore of considerable size was treated by magnetic separators. The possibilities of producing an ore rich enough for smelting purposes from some of the large deposits of lean magnetite have encouraged the introduction of a number of forms of separators, only a few of which, however, have proved of sufficient economic importance to be used.

ROASTING IRON ORES.

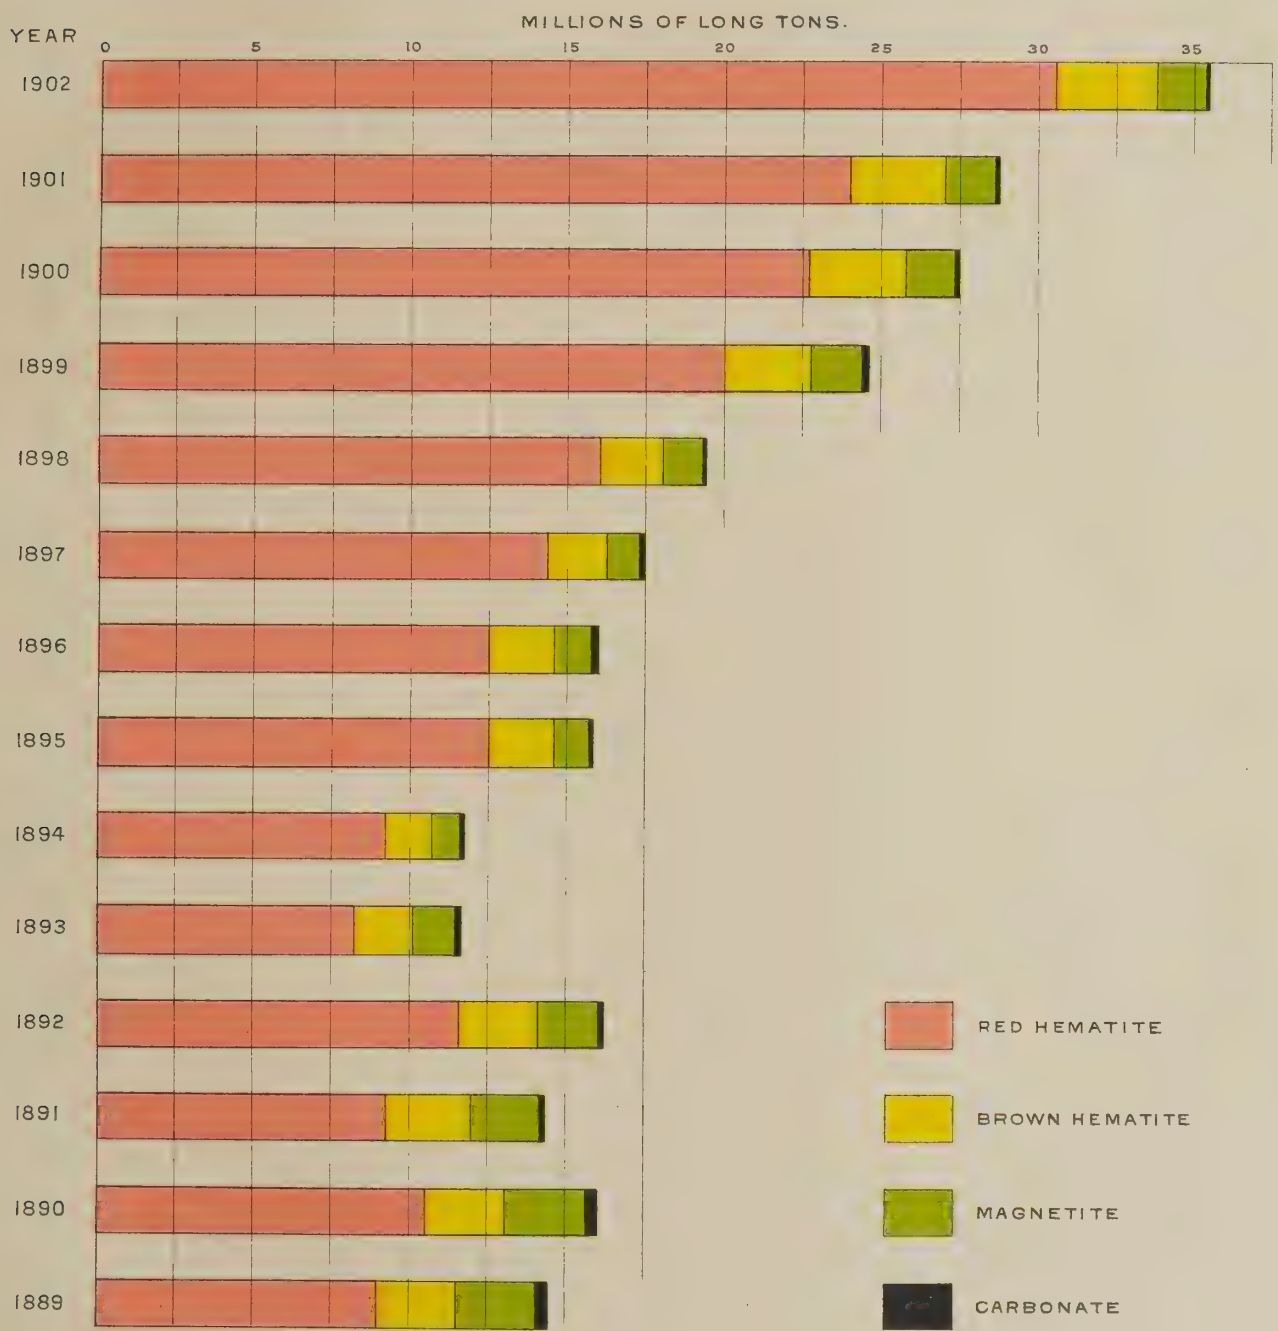
Among the methods used to beneficiate iron ores—that is, to improve their natural condition—is roasting, which may be applied for several purposes:

1. To drive off moisture.
2. While driving off moisture, to bake so as to separate the earthy matter which adheres to some ores and which often carries a large proportion of silica.
3. To eliminate carbonic acid, as in the case of the treatment of carbonate ores, thereby practically converting carbonate into brown hematite.
4. To reduce the percentage of sulphur carried in many ores, particularly magnetites.
5. To break up dense ores or make changes in the degree of oxidation and thus increase their reducibility.

Roasting was formerly done entirely in open heaps, formed of layers of wood (in some cases charcoal or fine bituminous coal supplementing the wood), alternating with layers of ore. These piles, when fire was applied to them, burned for months, and, in fact, the pile after being completed at one end was extended, while the end first finished was being roasted and the roasted ore taken from it to the furnace. An improvement in roasting was the introduction of cylindrical or rectangular masonry or metal kilns, in which fuel is mixed with the ore. In this way a more economical handling of the material is possible, and the results are under better control. In later years improvements in the roasting of ore have been practically confined to feeding kilns with gas, derived directly from the gas furnaces or obtained from gas producers. In the drying of brown hematites advanced progress is illustrated at the Shelby Iron Works, Alabama, where the Davis-Colby kiln using gas, roasts brown hematite ores. A statement by Mr. Charles J. Christian shows that taking green ore as it came from the washer, the yield was 43 per cent, and to flux this ore 23 per cent of limestone was required, while to smelt it 135 bushels of charcoal were necessary. When roasted in heaps, the moisture driven off, and the reduction of silica, which was obtained by screening, showed a yield of 50 per cent of iron, the requirements for smelting being 20 per cent of limestone and 105 bushels of charcoal. When gas kilns were introduced the yield of the ore was increased to 52 per cent, the proportion of flux was reduced to 18 per cent and the fuel consumption to 102 bushels of charcoal.

An experiment was also made in taking from a stock pile ore which had been roasted in heaps and reroast-

DIAGRAM I.—CLASSIFICATION OF IRON ORE PRODUCTION: 1889 TO 1902.



ing it. When the yield was increased to 56 per cent, the flux was reduced to 15 per cent of the ore burden, and the fuel consumption fell to 95 bushels of charcoal per ton of iron. In ordinary practice, Mr. Christian states, that the shrinkage of ore due to roasting and screening is about 23 per cent, water to the extent of 15 to 18 per cent being driven off; the balance is tailings in which there is some iron, but this loss is more than compensated for by the reduction in silica. The richer ore not only requires less flux and fuel, but also increases the product from a given furnace and reduces the cost of production correspondingly.

In roasting for the elimination of carbonic acid, most of the ores have been treated in piles, although some have been subjected to the roasting process in large kilns, some of these being 16 feet in diameter and 60 feet high; it is probable, however, that better results would be obtained in lower kilns. This treatment of the roasted ore is primarily to convert the carbonate into sesquioxide of iron by driving off the carbonic acid gas, and practically converting the clay ironstone ore into a brown hematite ore.

A number of years ago efforts were made in Scotland to use the upper portion of a blast furnace for this purpose, and one plant was erected in this country, the expectation being not only to drive off the carbonic acid gas from the ore, but to coke the raw coal as it passed down the furnace. This departure need not be further considered, as practically all the roasting is now done prior to feeding the ore to the furnace, and the results obtained encourage the continuance of this practice.

When sulphur is to be eliminated, the old practice of feeding solid fuel with the ore to heaps or kilns is less perfect than the new, as in the newer kilns using gas the ore is maintained at a high temperature, so as to oxidize more of the sulphur than would otherwise be the case. The most extensive use of ore roasting kilns is in the neighborhood of the Cornwall ore mines, Pennsylvania, where the average amount of sulphur in the ore as mined is 2.5 per cent. In kilns operated by fuel fed in alternate layers with the ore the sulphur is reduced about one-half; but in the kilns where gas is applied and the incandescent ore subsequently subjected to currents of air, the percentage of sulphur is reduced below 1 per cent. In addition to reducing the sulphur, the ore is improved in texture, and results obtained at the Wharton furnace in New Jersey show a very decided improvement independent of the elimination of sulphur. The roasting undoubtedly affects the physical character of the ore, making it more porous; it is, therefore, more readily attacked by the blast furnace gases. Where a component is to be eliminated in whole or in part, the driving off of this, whether it be water, carbonic acid, or sulphur, affects the texture of the mineral and makes it more readily reducible. It may be that the combined water in a magnetic ore, or the proportion which is hygroscopic, removed in the process of roasting, improves the texture of the ore; but this is not a matter upon which enough experiment has been made to speak with definiteness.

Mr. Edward Kelly, manager of the Wharton blast furnaces in New Jersey, states that the base of the ore mixture used in these furnaces is Hibernia magnetic ore, a close grained refractory ore, which is roasted to secure lower fuel consumption than is necessary when using it in the raw state. One furnace using 75 per cent Hibernia roasted ore, 12.5 per cent Hibernia raw ore, and 12.5 per cent soft Lake Superior hematite (the yield of this mixture approximating 50 per cent of iron) produced a ton of pig iron on a fuel consumption of 2,050 pounds. Another furnace, using 75 per cent Hibernia unroasted ore and 25 per cent of hematites, required 2,500 pounds of fuel to make 1 ton of metal. Therefore, the apparent saving at the furnace using Hibernia ore roasted is 450 pounds of fuel per ton of metal. With fuel at $4 per ton, this represents a saving of 90 cents per ton of pig iron, which the management attributed entirely to the roasting of Hibernia ore.

It may be considered as an established principle that whenever the metallic yield of an ore can be improved and the cinder making constituents reduced and yet left in sufficient quantity to permit satisfactory smelting, such a treatment is more economically done before charging the ore into the furnace than after it reaches the tunnel head, and it may be asserted that the beneficiating of ores in a blast furnace is the most expensive method to follow.

To determine the results to be obtained from roasting an iron ore a practical demonstration is essential. A laboratory test will be of value, but not nearly so satisfactory as a practical trial in a blast furnace. However, as such a trial is expensive, the laboratory experiment must be relied upon where there is no roasting appliance. Thus, by taking a sample of unroasted ore, crushing it fine, and similarly treating a sample of the same ore roasted, exposing this in tubes to the action of furnace gases, or of a current of carbon monoxide gas at a low red heat, the amount of oxygen in each case removed could be compared. Such a test would indicate whether a saving in fuel to offset the expense of roasting is probable. Blast furnaces using raw Lake Champlain magnetic ores require from 2,600 to 2,800 pounds of fuel per ton of metal, and in similar furnaces using Lake Superior ores 2,000 to 2,200 pounds per ton are required. With coke at $2.25 per ton the fuel saving of 600 pounds represents a decreased cost of 67.5 cents per ton of pig iron. When magnetites are roasted the smelting conditions approximate those prevailing with red hematites.

Another feature which has attracted attention in the Lake Superior region is the amount of moisture in the ore, and the proposition has been made to experiment

on a large scale with the idea of reducing this, as it limits the yield of the ore in the furnace and means additional freight by vessels to the lower lake and from the receiving docks to the blast furnaces.

ADVANTAGES OF MIXING IRON ORES.

The circumstances surrounding the mining, handling, and transporting of ores from the Lake Superior iron region seem to have a decidedly beneficial influence in securing the delivery to the blast furnaces of ores of nearly uniform composition. Similar conditions prevail elsewhere, but not to the same extent as in the Lake Superior region, because of the size of the deposits in that district, their liberal exploitation, their distance from points of consumption, and climatic conditions which limit the water transportation of ores.

All iron deposits vary more or less in different portions. This variation may be in the percentage of iron, silica, phosphorus, or other ingredients, and where a furnace depends on local mines, drawing upon them from day to day, receiving its stock practically as mined, greater irregularities are to be expected in the ore delivered than where ore passes through various handlings.

In the Lake Superior region the practice of the larger mines, although the mineral may nominally be of uniform character, is to win ore from several portions of the deposit simultaneously. The ores so won may be mixed in trains going to the ore docks, or trains may be made up entirely of ore from certain portions of the mines. Unless the chemical composition of this ore varies notably in the percentages of iron and phosphorus no segregation is necessary, and a number of bins in the shipping dock are filled with ore as it comes down in the railroad trains. A vessel brought to the side of the dock receives ore simultaneously, or nearly so, from a number of alternate pocket spouts, and is then moved to intermediate spouts. As the bins or pockets hold several carloads each there is a mixture in these and a further mixture in the hold of the vessel.

When the vessel reaches the receiving dock the ore is taken out by mechanical appliances, seldom by hand, the buckets delivering the ore either to stock piles on the receiving docks or directly into cars which convey it to the blast furnace.

As the shipping season on the Great Lakes covers usually about seven months in each year the blast furnaces must either carry stocks of ore at the plants or have them held at the receiving docks. Such accumulations of stocks result in securing a general mixture of ores from each mine which supplies the plant. Where work is prosecuted in the winter in the Lake Superior region, it is confined principally to dead work or exploration, largely to opening up drifts or chambers to facilitate mining during the next season. This ore taken out in the winter becomes thoroughly mixed in the stock pile and is subject to the same handling as above described. Even if the ore is delivered from vessels directly to cars, and these cars are dumped into the bins at the blast furnace, there is the admixture of ore from different parts of the mine, resulting from handling at the shipping and receiving docks, a mixture which it is not possible to secure from ores which are mined and sent directly to the furnace. The result is that the Lake Superior ores from different mines naturally have greater uniformity than those from other sections which may have ores of equal desirability. This may seem an unimportant matter when the average of the ores charged determine the basis on which to use them, but it exerts an effect on the operation of the furnace because there may be constant changes which affect the fluxing. For if at one time of a day the ore is low in silica, and at another time comparatively high, although the ore comes from the same bin, the fluxing will not be as perfectly equated as desired. As a consequence, the interior lining of a blast furnace is attacked, or the pig iron produced is more irregular than if the same relation between the gangue material in the ore and the fluxing medium was maintained steadily.

CLASSIFICATION OF IRON ORE PRODUCTION.

The rapid growth in production, both absolutely and proportionately, of red hematite in the United States is illustrated by Diagram I, which shows proportionately the quantity of red hematite, brown hematite, magnetite, and carbonate iron ores produced in 1889 (the classification being that of the Eleventh Census), and from 1890 to 1902, inclusive. While there has been a decided increase in red hematite, there has also been an advance, absolutely but not proportionately, in brown hematite, and a decline in the proportion of magnetite, although in late years this has been nearly stationary. The quantity of carbonate ore has constantly decreased.

Diagram II gives the relative quantities of each class of ore supplied by the more important producing states for the three census years 1880, 1889, and 1902. The illustration does not embrace the states producing small quantities. Even if the year 1900 had been selected for the comparison, the growth over 1889 would have been shown to be almost as great as that of 1889 over 1880. The increase of 1902 over 1889 is greater.

The plate shows that the entire production of Minnesota, and nearly all of the output of Alabama, Michigan, and Wisconsin, is classed as red hematite. It also shows the advance made in thirteen years, which is most notable in Alabama, Michigan, and Minnesota. The majority of the brown hematites are indicated as being mined in Alabama, Colorado, Georgia, Pennsylvania, Tennessee, and the Virginias, while the magnetites come principally from New Jersey, New York, and Pennsylvania. The production has

DIAGRAM II.- PRODUCTION OF IRON ORES IN THE UNITED STATES: 1902, 1889, AND 1880.

declined in New Jersey, New York, Pennsylvania, and in the group of states which includes "all others" not specially designated. Necessarily where the quantity of any one kind of ore has been too small to be shown on the plate it has been omitted. The legend of colors and the system of single and double cross hatching illustrate the different varieties of ores for the three census years covered by the diagram.

PRODUCTION OF IRON ORE IN LARGE MINES.

The proportion of the output of the United States contributed by large mines is a matter to which attention has been drawn, and Diagram III is presented to illustrate this. Data are not at hand showing the number of large mines and their total output, except for the years beginning with 1892, but the total production is given for the census years 1850, 1860, 1870, 1880, and 1889. The full lines of the column illustrate the total production of the ore, while the shaded portions show the quantity contributed by mines supplying over 50,000 tons. The total number of the larger mines in each year since 1891 appears in numerals at the sides of the respective columns. This showing demonstrates that while there has been an increase in the output of the smaller mines the bulk of the augmented product is due to the larger mines.

CONTEMPORANEOUS PRODUCTION OF IRON ORE IN THE UNITED STATES, GREAT BRITAIN, AND GERMANY.

Diagram IV shows for the years 1889 to 1902, inclusive, the relative quantities of iron ore produced in Great Britain, Germany, and the United States, and the proportion of the production of the United States supplied by the Lake Superior region. It will be noted that with the exception of 1894 the United States was a larger producer than either Great Britain or Germany. The strides by which these competitors have been distanced is illustrated by the showing for the interval from 1896 to 1902. A varying and practically decreasing tendency of the iron ore trade is illustrated for Great Britain, while a general advance is shown for Germany. The plate indicates the relation to the iron ore industry of the United States borne by the production of the Lake Superior region, which, since 1899, has been greater than the annual output of the mines of Great Britain, and since 1900 considerably in advance of the total product of the German mines.

168	Cost of supplies and materials	$9,005,608	$592,286	$137,450	$64,932	$2,639	$3,661,194
	Product:						
169	Quantity, long tons	35,567,410	3,574,474	[1]306,572	330,554	24,367	11,135,215
170	Value	$65,465,321	$3,936,812	[1]$1,084,424	$452,717	$46,911	$26,695,860

[1] Includes 13,275 tons of manganiferous iron ore valued at $52,371, used in the manufacture of spiegeleisen. The high average value per ton of the product in Colorado is due to the silver content, and to its availability for use as a fluxing medium when mixed with other gold and silver ores in the smelter.

MANGANESE ORE

30223—04——28

MANGANESE ORE.

By John Birkinbine.

Although manganese occupies an important position among metals, and is necessary in the manufacture of steel, of glass, and in the chemical industry, the production in the United States is small; and in 1902 may properly be discounted to the extent of 9,000 long tons reported as mined in Montana, which was not immediately available for consumption.

Table 1 is a comparative summary of the statistics for the industry as reported for the years 1902, 1889, and 1880.

Table 1.—*Comparative summary: 1880 to 1902.*

	1902	1889	1880
Number of mines	19	(1)	(1)
Number of operators	19	(1)	6
Salaried officials, clerks, etc.:			
Number	18	(2)	10
Salaries	$9,395	(2)	(2)
Wage-earners:			
Average number	194	432	222
Wages	$74,924	$123,958	[3] $46,610
Miscellaneous expenses	$3,845	(1)	(1)
Cost of supplies and materials	$17,728	(1)	$16,164
Product:			
Quantity, long tons	16,477	24,197	[4] 11,350
Value	$177,911	$240,559	[4] $102,700

[1] Not reported.
[2] Not reported separately.
[3] Includes salaries, not separable, of 10 salaried employees.
[4] Includes 637 tons, with an estimated value of $5,765, for which statistics of wage-earners, wages, and other expenses, etc., were not obtainable.

In the year 1902 the data are given in full, but for the previous census years some details are unobtainable, and in the year 1880 there was 1 mine from which no information was secured except the production of ore and its estimated value.

Of the 19 mines reported in 1902, 3 were in California, 6 each in Georgia and Virginia, 2 in Arkansas, and 1 each in Montana and South Carolina. The entire number was controlled by 19 operators, of whom 8 were individuals; 5, firms; and 6, incorporated companies.

Capital stock of incorporated companies.—Table 2, which follows, presents the statistics of capitalization of incorporated companies.

Table 2.—*Capitalization of incorporated companies: 1902.*

	United States.	California.	Georgia.	Virginia.
Number of incorporated companies	6	1	3	2
Number reporting capitalization	4	1	1	2
Capital stock:				
Total authorized—				
Number of shares	523,280	500,000	30	23,250
Par value	$2,855,000	$500,000	$30,000	$2,325,000
Total issued—				
Number of shares	123,330	100,050	30	23,250
Par value	$2,455,050	$100,050	$30,000	$2,325,000
Common—				
Authorized—				
Number of shares	517,280	500,000	30	17,250
Par value	$2,255,000	$500,000	$30,000	$1,725,000
Issued—				
Number of shares	117,330	100,050	30	17,250
Par value	$1,855,050	$100,050	$30,000	$1,725,000
Preferred—				
Authorized—				
Number of shares	6,000	.....	.....	6,000
Par value	$600,000	.....	.....	$600,000
Issued—				
Number of shares	6,000	.....	.....	6,000
Par value	$600,000	.....	.....	$600,000

Table 2 shows that the capital stock issued amounted to $2,455,050.

In 1889 the inquiries in regard to capital were different from 1902, the capital invested in lands, buildings and fixtures, machinery, tools and implements, live stock, cash, and stock of ore on hand being asked for at that census; therefore no comparison of any value can be made. According to the reports made in 1889 the total amount of capital invested was $2,188,950, divided as follows: Land, $1,618,650; buildings and fixtures, $98,700; machinery, tools, etc., $233,750; other items, including cash, $237,850.

Employees and wages.—In Table 10 the statistics of employees and wages are presented in detail by states. The different classes of salaried officials and wage-earners are given.

Of the total amount, $84,319, reported as paid for salaries and wages in the production of manganese ore, $74,924, or 88.9 per cent, was paid to wage-earners, and $9,395, or 11.1 per cent, to the salaried officials, clerks, etc.

Table 10 shows also the average number of wage-earners at specified daily rates of pay by occupations. Miners constituted 49.5 per cent of the total number of wage-earners, and of all miners 80.2 per cent were employed at rates from $1 to $1.24 per day. This low wage rate was due to the fact that most of the employees were unskilled, and the wages paid in the Southern states were lower, as a rule, than those prevailing in the Lake Superior region, where the climatic conditions are more severe. Of the 15 engineers, 3 received $2 or more per day. Miners' helpers formed a small class, constituting 1.5 per cent of the total wage-earners. The class of "all other wage-earners" numbered 56, composed chiefly of ordinary laborers. Of these workmen 92.9 per cent received from $1 to $1.24 per day, the same general rate as that of many of the miners, while 7.1 per cent received $1.25 or more.

The average number of wage-earners, men and boys, employed during each month of the year, is also shown in Table 10. With the exception of the mines in Georgia, where employment was practically constant, the average number of wage-earners varied considerably. It will be noted that during the summer and fall months the average number of wage-earners in Virginia was considerably augmented, falling off during the winter and early spring months. In California the operations practically closed in August and remained in this condition until the end of the year.

For the various mechanical operations requiring power at the mines there were 11 steam engines of 354 horsepower.

Production.—To show the relative production of manganese ores in 1902 and in each of the nine years preceding, Table 3 is presented. It gives the production, total value, and average value per ton of ore at the mines.

TABLE 3.—*Production of manganese ores: 1893 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	Quantity (long tons).	Value.	Average value per ton.
1893	7,718	$66,614	$8.63
1894	6,308	53,635	8.50
1895	9,547	71,769	7.52
1896	10,088	90,727	8.99
1897	11,108	95,505	8.60
1898	15,957	129,185	8.10
1899	9,935	82,278	8.28
1900	11,771	100,289	8.52
1901	11,995	116,722	9.73
1902	16,477	177,911	10.80

The following table shows the quantity, total value, and average value per ton of the manganese ore produced by states in the year 1902. The production of South Carolina was a sample shipment, the value of which was estimated:

TABLE 4.—*Production and value, and average value per ton, of manganese ores, by states: 1902.*

STATE.	Quantity (long tons).	Value.	Average value per ton.
United States	16,477	$177,911	$10.80
Arkansas	(1)	(1)	5.15
California	846	10,175	12.03
Georgia	3,500	20,830	5.95
Montana	(1)	(1)	13.00
South Carolina	(1)	(1)	5.00
Virginia	3,041	29,444	9.68
Arkansas, Montana, and South Carolina	9,090	117,462	.....

[1] Not given separately, in order to avoid disclosing operations of individual establishments.

In producing the total for 1902, 16,477 tons, valued at $177,911, 6 states contributed, viz: Montana, Georgia, Virginia, California, Arkansas, and South Carolina, in the order named.

The following table gives the production by states for the census years 1889 and 1902, and for each of the twelve years intervening. The figures for the years between 1889 and 1902 were obtained from the statistical reports of the United States Geological Survey.

TABLE 5.—*Production of manganese ores, by states: 1889 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	United States (long tons).	Virginia (long tons).	Georgia (long tons).	Arkansas (long tons).	All other states (long tons).
Total	197,814	90,001	44,431	33,167	30,215
1889	24,197	14,616	5,208	2,528	1,845
1890	25,684	12,699	749	5,339	6,897
1891	23,416	16,248	3,575	1,650	1,943
1892	13,613	6,079	826	6,708	.....
1893	7,718	4,092	724	2,020	882
1894	6,308	1,797	1,277	1,934	1,300
1895	9,547	1,715	3,856	2,991	985
1896	10,088	2,018	4,085	3,421	564
1897	11,108	3,650	3,332	3,240	886
1898	15,957	5,662	6,689	2,662	944
1899	9,935	6,228	3,089	356	262
1900	11,771	7,881	3,447	145	298
1901	11,995	4,275	4,074	91	3,555
1902	16,477	3,041	3,500	82	9,854

The output of the three states producing the greatest quantities, viz, Virginia, Georgia, and Arkansas, as well as the total for the United States, shows a marked falling off since the year 1889, when the total mined in Virginia was 14,616 long tons; in Georgia, 5,208 long tons; in Arkansas, 2,528 long tons; and in other states, 1,845 long tons; a total of 24,197 long tons, valued at $240,559.

In the year 1902 the production of manganese ore per wage-earner was greater than in either 1889 or 1880, being 85 tons, as against 56 tons in 1889 and 49 tons in 1880. But for the census year 1889 the total number of persons employed is given for the time during which the mines were operated, whereas for the census year 1902 the average number is the number that would be required at continuous employment throughout the year.

Imports of manganese ore.—The United States is the largest manufacturer of steel in the world. In the processes of the conversion of iron into steel spiegeleisen or ferromanganese obtained from manganese or manganiferous ore is a necessity. Consequently, owing to the insufficient supply of this mineral obtained in the United States, large quantities are imported.

Through the courtesy of the Bureau of Statistics of the Department of Commerce and Labor, the following table has been prepared showing the importation of manganese ore into the United States during the calendar year 1902, by countries:

TABLE 6.—*Imports of manganese ore, by countries: 1902.*

COUNTRY.	Quantity (long tons).	Value.
Total	235,576	$1,931,282
Belgium	165	1,962
Brazil	102,550	1,006,969
British East Indies	64,170	352,487
Colombia	700	3,385
Cuba	36,294	285,571
Germany	2,155	68,241
Japan	2,481	37,064
Nova Scotia, New Brunswick, etc	59	2,311
Quebec, Ontario, etc	140	820
Russia	3,338	24,581
Spain	10,464	48,098
Turkey in Europe	12,609	88,979
United Kingdom	451	10,814

Table 6 shows that in the census year 1902, 235,576 long tons were imported, valued at $1,931,282, an average of $8.20 per ton. The valuations placed on this ore are as invoiced at the point of shipment, and do not include the cost of ocean freight to the United States or rail charges to points of consumption. The principal contributor was Brazil, with a total of 102,550 long tons, valued at $1,006,969. The other contributing countries were India, Cuba, Turkey, Spain, Russia, Japan, Germany, Colombia, United Kingdom, Canada, and Belgium, in the order named.

The following table gives the quantity and value of manganese ore imported into the United States from 1889 to 1902, inclusive:

TABLE 7.—*Imports of manganese ore: 1889 to 1902.*

YEAR.	Quantity (long tons).	Value.
Total	1,436,950	$13,028,432
1889	4,286	78,391
1890	34,154	516,900
1891	28,825	380,618
1892	58,572	840,811
1893	68,113	880,238
1894	44,655	432,561
1895	86,111	747,910
1896	31,489	250,468
1897	119,961	1,023,824
1898	114,885	831,967
1899	188,349	1,584,528
1900	256,252	2,042,361
1901	165,722	1,486,573
1902	235,576	1,931,282

Table 7 shows that, with the exception of the year 1900, the largest quantity imported was in the year 1902. It will be of interest to note that in the year 1889, 24,197 long tons of domestic manganese ore were produced and 4,286 long tons of manganese ore imported; whereas, in the year 1902, 16,477 long tons of domestic manganese ore were mined and 235,576 long tons imported. In the fourteen years under consideration the manganese mines of the United States have contributed 197,814 long tons, while the importations have amounted to 1,436,950 long tons; therefore, 87.9 per cent of the manganese ore used in the United States during these fourteen years came from foreign countries. In the year 1902 the quantity of imported manganese ore represented 93.5 per cent of the total consumption. In 1902 the greater portion, 200,434 long tons, of the manganese ore brought to this country was received at the port of Baltimore, Maryland.

World's production.—As the greater portion of the manganese ore consumed in this country is obtained from foreign nations, Table 8 is presented showing the production of the more important manganese producing countries. For each country the latest reliable statistics obtainable have been used, the years to which the figures relate being indicated in the table.

TABLE 8.—*World's production of manganese ores.*

COUNTRY.	Year.	Production (long tons).	COUNTRY.	Year.	Production (long tons).
North America:			Europe—Continued.		
United States	1902	16,477	Italy	1902	2,438
Canada[1]	1902	154	Portugal	1901	[2]904
Cuba[1]	1902	39,628	Russia	1900	884,200
South America:			Spain[1]	1902	61,949
Brazil[1]	1902	156,269	Sweden	1902	2,805
Chile[1]	1901	31,477	Turkey[1]	1902	49,210
Europe:			Asia:		
Austria	1902	5,557	India	1902	157,780
Bosnia and Herzegovina	1902	5,669	Japan	1901	15,858
France	1901	21,948	Java[1]	1899	1,388
Germany	1901	49,025	Oceania:		
Greece	1901	13,945	New Zealand	1901	208
Hungary	1902	7,231	Queensland	1901	218
			South Australia	1901	192

[1] Exports. [2] Metric tons.

Russia has for years been the largest producer, the bulk of the ore coming from the Caucasus region, the mines being located in the Secharopan district of the government of Kutais, not far from the extreme eastern shore of the Black Sea, near Poti. India has important deposits which have been actively exploited in late years, most of those from which shipments are made being located in the presidency of Madras. In the year 1902 Brazil, where the manganese industry has been lately developed, took third position; most of the ore mined being obtained in the Minas Geraes and Nazareth districts, located in the states of Minas Geraes and Bahia, respectively, in the eastern central portion of the country. Spain, Turkey, Cuba, and Chile have

important deposits of manganese ores, and small quantities are obtained in the Austrian Empire, France, Germany, Greece, Italy, Portugal, Sweden, Japan, Canada, New Zealand, and in Australia. Failure to appreciate the necessity of careful preparation of ores has restricted the quantities shipped from some of these countries.

In the United States the manganese deposits exploited are either of comparatively small extent, or the mineral contains phosphorus or silica in such proportions as to limit the transportation value of the ore, or the deposits are too far removed from markets where the ore would be consumed to make their development at present desirable. Manganese, however, either in the form of an ore or associated with iron or silver, has been supplied in large quantities. The bulk of this, being applied to the manufacture of steel, is sold under limitations, wherein the modicum of phosphorus and the percentage of silica, calculated on sliding scales, affect the prices paid for the ore, thus seriously interfering with the development of some properties where the quantity is apparently sufficient, but the quality is not desirable.

Value of manganese ores.—Manganese ores are valued from a sliding scale for the ore delivered f. o. b. cars at the large steel works, the prices being based on ores containing not more than 8 per cent of silica or more than one-tenth of 1 per cent of phosphorus. To illustrate, the following may be taken as the prices for manganese ores delivered in the Pittsburg (Pa.) district, they being subject to change without notice unless otherwise agreed:

Prices paid for manganese ore delivered in the Pittsburg (Pa.) district.

MANGANESE.	PRICE PER UNIT. Iron (cents).	Manganese (cents).
Ore containing—		
Above 49 per cent	6	28
46 to 49 per cent	6	27
43 to 46 per cent	6	26
40 to 43 per cent	6	25
37 to 40 per cent	6	24
34 to 37 per cent	6	23
31 to 34 per cent	6	22

These prices are subject to deductions as follows: For each 1 per cent of silica in excess of 8 per cent, 15 cents per ton, and for each two-hundredths of 1 per cent of phosphorus in excess of one-tenth of 1 per cent, 1 cent per unit of manganese. Settlements are based on analyses of the ores dried at 212° F., the percentage of moisture in samples when taken being deducted from the weight.

The value of ore at the mines would be practically the price obtained for the ore delivered in the Pittsburg district, as above, less transportation charges.

In the manufacture of steel for various purposes and by different methods, the metallic manganese required ranges from about 9 to 40 pounds per ton of ingots produced, the average for the entire steel industry approximating 20 pounds of metallic manganese, or about 25 pounds of high-grade ferromanganese per ton of ingots made.

Manganiferous iron ores.—In addition to the true manganese ore produced, considerable quantities of manganiferous iron ore are obtained in the United States, the statistics of which are included in the report on iron ores. In the year 1902 there was obtained in the state of Colorado 13,275 long tons of this class of ore, in which the percentage of manganese varied from 18 to 32 per cent, having a total reported value at the mines of $52,371. This ore was all used in the production of spiegeleisen at steel works and should properly be classed as manganese ore, but owing to the impossibility of segregating the proportion of wage-earners, wages, and other expenses chargeable in the different mines from which this ore was obtained, the data were included in the statistics of iron ore. In the Lake Superior region, also, considerable amounts of iron ore are won which carry small percentages of manganese, but, as a rule, this does not exceed 1 per cent. In Virginia, too, a small quantity of manganiferous iron ore has been secured while mining true manganese ore.

The following statement shows the quantity, percentage of manganese, value at the mine, and average value per ton of manganiferous iron ores mined in the United States during the year 1902:

Production of manganiferous iron ores: 1902.

LOCALITY.	Quantity (long tons).	Per cent of manganese.	Value.	Average value per ton.
Total	901,214	1 to 32	$2,001,626	$2.22
Colorado	13,275	18 to 32	52,371	3.95
Lake Superior region	884,939	1 to 10	1,946,255	2.20
Virginia	3,000	(1)	3,000	1.00

[1] Not given.

The following table presents the production, total value at the mine, and average value per ton of the manganiferous iron ores obtained in the United States from 1889 to 1902, inclusive, the statistics for the years between the two censuses being obtained from the reports of the United States Geological Survey.

TABLE 9.—*Production of manganiferous iron ores: 1889 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	Quantity (long tons).	Value.	Average value per ton.
1889	83,434	$271,680	$3.26
1890	61,863	231,655	3.74
1891	132,511	314,099	2.37
1892	153,373	354,664	2.31
1893	117,782	283,228	2.40
1894	205,488	408,597	1.99
1895	125,729	233,998	1.86
1896	338,712	726,413	2.14
1897	202,304	343,784	1.70
1898	287,810	429,302	1.49
1899	761,845	1,147,047	1.51
1900	377,577	1,037,314	2.75
1901	574,489	1,475,084	2.57
1902	901,214	2,001,626	2.22

In the year 1889 the total production of manganiferous iron ores in the United States was 83,434 long tons, valued at $271,680. In 1902 the production was 901,214 long tons, an increase of 817,780 long tons, or nearly tenfold.

Argentiferous manganiferous iron ores.—In the state of Colorado argentiferous manganiferous iron ore is obtained from precious metal mines. This ore, containing an insufficient quantity of silver to make it valuable on that account, finds a ready market as a flux for use in smelters. The ores which are mined chiefly in the vicinity of Leadville, Colo., are classed usually as carbonates, sulphides, oxides, and siliceous ores. The first two classes are dependent for their value upon the carbonates and sulphides of lead and silver, but the oxides and siliceous ores may or may not be dependent on the precious metal content, and unless the value of the ores for smelting purposes was greater than the charge for the extraction of the precious metal (approximating $12 per ton) they have been considered as iron ores and included in the report on that mineral. The total quantity of these ores (which contain varying percentages of manganese) mined in the year 1902 was 194,132 long tons, valued at $908,098, an average of $4.68 per ton. In 1889, 64,987 long tons of argentiferous manganiferous ores valued at $227,455, were mined in the United States, the average value being $3.50 per ton. This shows an increase in 1902 of 129,145 tons, or nearly twofold, while the average value per ton rose to $4.68.

Manganiferous zinc ores.—The franklinite mines, located in northern New Jersey, produce ores which carry, in addition to the zinc content, iron and manganese. The clinker resulting from treatment for the removal of zinc is utilized in the production of spiegeleisen. The quantity of this class of material produced in 1902 was 65,246 long tons, valued nominally at $1 per ton. The production in 1889 was 43,648 long tons, valued at $54,560, or an average value of $1.25 per ton.

A résumé of the useful minerals produced in the United States in 1902, which contained manganese in notable proportions, is given in the following statement, in which the figures for the year 1889 have been included for purposes of comparison:

Useful minerals produced containing manganese in notable proportions: 1902 and 1889.

	1902			1889		
	Quantity (long tons).	Value.	Average value per ton.	Quantity (long tons).	Value.	Average value per ton.
Total	1,177,069	$3,152,881	$2.68	216,266	$794,254	$3.67
Manganese ores	16,477	177,911	10.80	24,197	240,559	9.94
Manganiferous iron ores	901,214	2,001,626	2.22	83,434	271,680	3.26
Manganiferous silver ores	194,132	908,098	4.68	64,987	227,455	3.50
Manganiferous zinc residuum	65,246	65,246	1.00	43,648	54,560	1.25

The total quantity of manganese and manganiferous ores mined in the United States in 1889 was 216,266 long tons, valued at $794,254, whereas in 1902 it had risen to 1,177,069 long tons, valued at $3,152,881, the increase being confined entirely to manganiferous ores, the production of true manganese ores having decreased.

REVIEW OF THE INDUSTRY BY STATES.

The conditions surrounding and affecting the production of manganese ores in different states are summarized as follows:

Arkansas.—Manganese ores occur chiefly in two districts of Arkansas—(a) the Batesville district, in Independence and Izard counties, in the northeastern part of the state; and (b) in the southwestern section, extending from Pulaski county on the east to Pope county and Indian Territory on the west. The mining in the latter district has been limited and practically all of the ores mined have come from the Batesville region, where they occur in residuary clays, derived from the decay of limestone.

Ore was discovered near Batesville about 1840, and in 1850 small quantities were sent to Boston, New York, Philadelphia, and Chicago. The maximum output was in the year 1892, when 6,708 long tons were produced. Lately, however, there has been a marked decline, for although some of the ores of Arkansas carry satisfactory percentages of manganese, their high phosphorus content, in addition to the distances from points of con-

sumption and the expense of mining, has rendered the winning of many of them unprofitable.

In 1902, 82 tons of manganese ore were secured. According to the Eleventh Census the amount of manganese ore mined in Arkansas in 1889 was 2,528 tons. The total production of the district from 1850 to 1902, inclusive—some of the figures being estimates—was 49,974 tons.

California.—California contains a number of deposits of manganese ore, some of which are reported as of high quality, and have been largely employed in chlorination works for the reduction of gold ores. In 1902 deposits in Alameda, San Joaquin, Santa Clara, and Stanislaus counties were operated, the amount produced being 846 tons. The quantity mined in 1889 was 53 tons. The total production of manganese ore in California from 1874 to 1902, inclusive, as near as can be ascertained, amounts to 11,358 tons, the production in 1902 being the maximum.

Colorado.—A large amount of iron ore, which contains a mixture of iron, manganese, and the precious metals, is produced in Colorado. The greater portion of this ore, which carries an insufficient amount of the precious metals to make it valuable on that account, is used as a flux in smelters, while some of that which is higher in manganese content is forwarded to steel works, where it is utilized in the manufacture of spiegeleisen. The figures for the production of these classes of ores, which have been included in the census report on iron ores, are inserted here as an item of interest. The comparison of the production in the year 1902 with that of the census year 1889 is shown in the following statement:

Production of manganiferous ores in Colorado: 1902 and 1889.

ORE.	1902 (long tons).	1889 (long tons).
Total	207,407	67,062
Manganiferous iron ores used for producing spiegeleisen	13,275	2,075
Manganiferous silver ores	194,132	64,987

Georgia.—The manganese ores of Georgia are won from two districts—the Cartersville district, located near the town of that name in Bartow county, and the Cave Springs district, in Floyd and Polk counties. The deposits in the latter district have been but little worked, nearly the entire production coming from the Cartersville district. The mines which were active in the year 1902 were all located there. Some of these manganese ores are of good quality, but others contain comparatively high percentages of phosphorus and are lower in manganese. The total amount of manganese ore obtained in Georgia in 1902 was 3,500 long tons, while in 1889 it was 5,208 long tons, showing a decrease of 1,708 tons, or 32.8 per cent. The total production of this district from 1866 to 1902, inclusive—the output for some of the years being estimated—was 91,594 long tons, the maximum production being 9,024 long tons, in 1887.

Montana.—In previous years Montana has been an unimportant contributor of manganese ore, but in 1902 a large quantity of ore was reported as mined, but not shipped, from two deposits in this state. Although most of this will not be immediately available for use, the reported product is included in the statistical data. The deposits are located at a considerable distance from steel works, which are the largest consumers of this ore, and unless satisfactory rail rates are secured it is doubtful whether this state will become an important producer in the immediate future.

South Carolina.—As has been stated, the 8 tons of manganese ore which were secured near Greenwood, in this state, were shipped as a sample; no systematic mining has been reported.

Virginia.—Virginia was the most important producer of manganese ore in the United States in 1889, a total of 14,616 long tons being secured. Nearly all of this came from the Crimora mine, located in Augusta county, but after a few years this mine showed signs of exhaustion and mining operations were suspended. It has, however, been reopened in the hope of encountering new reserves of ore, and if these expectations are realized the state may again become an important contributor. The 1902 output was only 3,041 tons. The aggregate production from 1880 to 1902, inclusive, was 191,067 tons, the output of the year 1886, when 20,567 long tons were mined, being the maximum.

Table 10 is a detailed summary of the statistics of the manganese industry for the United States, by states, in 1902.

DESCRIPTIVE.

Manganese is not found in a metallic state in nature, but usually occurs as an oxide, carbonate, or silicate in combination with one or more of the other elements. The oxides are the most common of manganese minerals, but rhodonite and rhodochrosite—the silicate and the carbonate—are frequently met. The commercially important ores are the oxides—pyrolusite, psilomelane, braunite, manganite, hausmannite, and wad—brief descriptions of which follow:

Pyrolusite, a peroxide or binoxide of manganese (MnO_2), is of an iron-black color, giving a black streak on a test plate, with a hardness of 2 to 2.5 and a specific gravity of 4.8 to 5. If pure, it would yield 63.2 per cent of manganese and 36.8 per cent of oxygen. It is used in the manufacture of ferromanganese, in the production of chlorine, and in freeing glass from the brown or green color.

Psilomelane, one of the common ores of manganese, usually occurs associated with pyrolusite. It is also a binoxide or peroxide of manganese, but contains varying amounts of combined water, and often potassium, barium, and iron. It is generally massive (i. e., not crystallized), has a hardness of 5 to 6 (much harder than pyrolusite), and a specific gravity from 4 to 4.4. It is black, steel-blue, or greenish-black in color. Its uses are the same as those of pyrolusite, and by some it is considered a hydrated variety of this mineral. The manganese contents range, when the ore is pure, from 45 to 60 per cent.

Braunite is an anhydrous oxide of manganese (Mn_2O_3), usually containing silica. It is a black or brownish-black ore, generally crystalline, giving the same streak as pyrolusite on the test plate and having a submetallic luster. It has a hardness of 6 to 6.5 and a specific gravity of 4.8. When pure, which is rarely the case, it contains 69 per cent of metallic manganese.

Manganite, a hydrous sesquioxide of manganese ($Mn_2O_3H_2O$), is of a steel-black or iron-black color, with a hardness of 4 to 4.5 and a specific gravity of 4.3 to 4.4. When the water is removed from manganite it changes to pyrolusite, hausmannite, or braunite; in some cases the latter minerals are supposed to be altered manganite, this being especially true of pyrolusite.

Hausmannite, a double protobinoxide of manganese (Mn_3O_4), is of a brownish-black color and of a submetallic luster, with a hardness of from 5 to 5.5 and a specific gravity of 4.7. It is a rare mineral, which, if pure, would contain 72.1 per cent of manganese and 29.9 per cent of oxygen.

Wad, or bog manganese, is an impure peroxide of manganese, with peroxide of iron carrying from 10 to over 25 per cent of water, often several per cent of oxide of cobalt or copper, and sometimes nickel. Its hardness is from 1 to 6 and its specific gravity 3 to 4. The color varies from brown to black. It occurs in irregular masses in clay as solid beds several feet thick, but on account of its impurities is seldom used as a source of manganese, but is occasionally employed as the base for black or brown paint.

Both manganese and manganiferous ores are applied to the industrial arts, their uses being summarized as follows: As an alloy with iron in the production of ferromanganese and spiegeleisen manganese is employed in the conversion of iron into steel. It is also alloyed with copper, either with or without iron in manganese bronze, and with aluminum, zinc, copper, and silicon in silver bronze, and with aluminum, zinc, tin, lead, and magnesium.

Manganese ore is employed as a flux in smelting precious metals; it is utilized as an oxidizer in chemical works in the manufacture of chlorine and bromine; as a decolorizer of glass and also for coloring it; as a drier for varnishes and paints; for Leclanche batteries in the preparation of oxygen in a small way; in the manufacture of disinfecting permanganates, etc. It is also used as coloring material in printing, in pottery and brick, and for green and violet paints. Some varieties of manganese ore are also utilized in a limited way in medicine, in chemical laboratories, and in jewelry manufacture.

Most of the manganiferous ores are applied either to the production of spiegeleisen or as an integral part of the charge of an iron producing plant, or are fed to silver smelters as a flux.

TABLE 10.—DETAILED SUMMARY: 1902.

	United States.	California.	Georgia.	Virginia.	All other states.[1]

LEAD AND ZINC ORE

LEAD AND ZINC ORE.

By Isaac A. Hourwich, Ph. D.

The present report deals only with mines producing nonargentiferous lead and zinc ores. The statistics relative to the production of lead and zinc incidental to mining for gold and silver are treated in the report on gold and silver.

The combination of the mining and smelting of lead in early times precluded separate statistics for each process. The census data relating specifically to lead mining were first presented in 1870. The earliest mention of zinc ore in census reports was in 1860, when 2 mines were reported with 52 employees and a value of product aggregating $72,600. Lead and zinc mining was reported at the census of 1870, and at the two subsequent censuses. Differences in the scope of the inquiry, and in the method of presenting the results, materially impair the value of the statistics of all these years for comparative purposes. At the Eleventh Census no statistics of wages, or of other expenditures, were shown for the zinc mines of southwestern Missouri; only the output, amounting to 186,262,308 pounds, valued at $2,024,057, was reported for that district. The statistics of the Eleventh Census are, therefore, omitted from the comparative summary given in the following table:

Table 1.—*Comparative summary: 1902, 1880, and 1870.*

	1902	1880	1870
Number of mines	559	206	[1] 127
Number of operators	557	(2)	(2)
Salaried officials, clerks, etc.:			
Number	910	420	(2)
Salaries	$826,327	(3)	(2)
Wage-earners:			
Average number	7,881	7,063	1,714
Wages	$4,329,271	[3] $2,640,265	$600,628
Contract work	$108,607	(2)	(2)
Miscellaneous expenses	$2,092,001	(2)	(2)
Cost of supplies and materials	$2,511,675	$331,970	$78,687
Value of product	[4] $14,600,177	$3,837,161	$1,524,884

[1] Establishments.
[2] Not reported.
[3] Salaries included in wages.
[4] Includes $83,781, value of product of custom mills, and $1,913,810, for which the number of mines was not reported.

In order to make the data of the Eleventh Census comparable with those of the Twelfth, a summary of all mines, exclusive of the zinc mines of Missouri, is presented for the two years in the following table:

Table 2.—*Comparative summary, exclusive of zinc mines in Missouri: 1902 and 1889.*

	1902	1889
Number of mines	238	(1)
Salaries	$404,836	[2] $21,033
Wages	$2,042,821	$1,220,766
Contract work	$32,761	$34,511
Miscellaneous expenses	$495,388	$242,649
Cost of supplies and materials	$1,153,129	$407,938
Value of product	$5,713,601	$2,780,122

[1] Not reported.
[2] Salaries of foremen included in wages.

The total number of lead and zinc mines reported for the United States in 1902 is 559, and the total number of operators 557; the difference represents 2 incorporated companies in Virginia that operated iron mines in connection with zinc mines and are included in the report on iron mines; the statistics for the zinc mines, however, except those of capitalization, were segregated and are shown in this report.

Because of the prevalence of the leasing system in the operation of the lead and zinc mines, the terms "mine" and "operator" are indefinite in their meaning. The unit of these tables represents every operation for which a separate return was made. If the land was operated by its owner, the owner's report was included in the tables. Leasing companies whose business was confined to distributing land in small lots among operators and to drawing royalties, were not included in the general tables, unless some hired labor was employed by them in developing the mines. If the land was operated by a lessee with the help of hired labor, the lessee's report was tabulated. The numerous small sublessees, personally working in the mines, as a rule did not report; only 56 operators of that class made returns, and the

statistics for these are included in the tables. The share contributed by this class of small operators to the lead and zinc production of Kansas and Missouri is shown in the following table:

TABLE 3.—DISTRIBUTION OF THE VALUE OF THE LEAD AND ZINC PRODUCTION OF KANSAS AND MISSOURI BY CLASS OF OPERATORS: 1902.[1]

CLASS OF OPERATOR.	KANSAS.				MISSOURI.			
	Total.	Per cent of total.	Lead ore.	Zinc ore.	Total.	Per cent of total.	Lead ore.	Zinc ore.
Total	$707,026	100.0	$163,084	$543,942	$12,513,021	100.0	$5,520,211	$6,992,810
Operators reporting	342,943	48.5	67,144	275,799	10,496,884	83.9	5,073,363	5,423,521
Sublessees not reporting	364,083	51.5	95,940	268,143	2,016,137	16.1	446,848	1,569,289

[1] Exclusive of the production of custom mills valued at $73,189.

Of the 557 operators reporting, only 90 owned the mines they operated, 461 were first lessees or sublessees, and 6 failed to report as to ownership. The Missouri lead and zinc mine inspector's list of mines enumerates 151 landowners; according to census returns for Missouri, 61 operators were owners of the lands they operated, which leaves 90 landowners whose mines were operated under the leasing system. The above number of lessees and sublessees does not include the numerous class of small sublessees who do the work themselves with pick and shovel. The number of such sublessees reported by landowners was 638, of whom 632 were reported from Missouri. This number, however, is very far from complete, an accurate count being precluded by the shifting character of this class of miners.

The unincorporated form of business organization was the prevailing form among operators. There were in all 398 unincorporated concerns and 161 corporations directly engaged in operating the mines. Judged by the volume of production, the corporations held a place of greater prominence in the lead-zinc mining industry than that held by unincorporated operators.

The share of each class of operators in the total production and the average output per mine are shown in the following table:

TABLE 4.—*Classification of lead and zinc mines, by character of ownership: 1902.*

CHARACTER OF OWNERSHIP.	Number of mines.	PRODUCT.		
		Value.	Per cent of total.	Average per mine.
Total	559	$14,600,177	100.0	[1] $22,695
Incorporated company	161	8,823,159	60.4	54,802
Firm	323	3,073,822	21.1	9,516
Individual	66	670,201	4.6	10,155
Other form	9	119,185	0.8	13,243
Form not reported		1,913,810	13.1	

[1] Exclusive of those for which character of organization was not reported.

A summary for incorporated and unincorporated operators is presented in the following table:

TABLE 5.—*Summary for incorporated and unincorporated operators: 1902.*

	Total.	Incorporated.	Unincorporated.
Number of mines	[1] 559	[1] 161	398
Salaries	$826,327	$634,177	$192,150
Wages	$4,329,271	$2,928,788	$1,400,483
Contract work	$108,607	$49,903	$58,704
Miscellaneous expenses, exclusive of royalties	$566,633	$512,319	$54,314
Royalties	$1,525,368	$584,149	$941,219
Work on share of product	$234,461	$189,597	$44,864
Cost of supplies and materials	$2,511,657	$1,771,672	$739,985
Value of product, total	[2] $14,600,177	[3] $8,823,159	[4] $5,777,018
Lead—			
Quantity, short tons	[5] 132,330	[5] 105,409	26,921
Value	$5,850,721	$4,530,281	$1,320,440
Zinc—			
Quantity, short tons	[6] 491,332	[6] 326,576	164,756
Value	$8,665,675	$4,277,660	$4,388,015

[1] Includes 2 corporations whose capitalization is reported under iron ore.
[2] Includes $83,781, value of product from custom mills.
[3] Includes $15,218, value of product from custom mills.
[4] Includes $68,563, value of product from custom mills.
[5] Includes 10,023 tons, valued at $432,231, product of small operators not reporting.
[6] Includes 60,685 tons, valued at $1,533,548, product of small operators not reporting.

From the preceding table the average value per ton of lead ore is computed to be $44 for the product of all mines, $43 for incorporated and $49 for unincorporated operators. Average values of zinc ore drawn from the preceding statement would be misleading, inasmuch as the quantity and the value of zinc ore for incorporated companies and, consequently, for all mines in the United States, are affected by the returns of 3 large eastern mines—1 in New Jersey and 2 in Virginia—that produce low grade ore. In the following statement these mines are eliminated, and the average values, relating only to western ores, which are approximately of the same grade, disclose no substantial difference between incorporated and unincorporated forms of ownership:

Quantity and value of high grade zinc ore, mined by incorporated and unincorporated operators: 1902.

CHARACTER OF OWNERSHIP.	Short tons.	Value.	Average per ton.
Total	289,800	$8,022,522	$27.68
Incorporated	125,044	3,634,507	29.07
Unincorporated	164,756	4,388,015	26.63

Capital stock of incorporated companies.—The capitalization of the incorporated companies is shown in the following table:

TABLE 6.—CAPITALIZATION OF INCORPORATED COMPANIES: 1902.

	United States.[1]	Colorado.	Illinois.	Kansas.	Missouri.	Wisconsin.	All other states.[2]
Number of incorporated companies	159	1	4	8	129	15	2

Interest paid	$226,200			$6,900	$59,300		$160,000
Assessments levied	$79,531				$64,531	$15,000	

[1] In addition there were 2 incorporated companies owning 2 mines in Virginia, and also owning and operating iron ore mines in West Virginia. The capitalization of these companies is reported under iron ore, since the capitalization for each industry can not be segregated.
[2] Includes 1 in New Jersey and 1 in New York.

The division of the capital stock into common and preferred is not in general use among the lead and zinc mining corporations. In the following statement the 159 operating companies are grouped in accordance with the class of stock reported by them:

Incorporated companies grouped by class of stock: 1902.

CLASS OF STOCK.	Number of incorporated companies.	AMOUNT ISSUED.		
		Total.	Common.	Preferred.
Total	159	$45,923,641	$43,551,286	$2,372,355
Both common and preferred	14	8,760,661	6,388,306	2,372,355
Common only	145	37,162,980	37,162,980	

The total bonded indebtedness reported was: Authorized, $12,575,000; issued, $5,403,250; the interest paid was $226,200. Among the companies for which a bonded indebtedness was reported were 2 companies whose capital stock and bonds represented manufacturing plants in addition to mining property. With these companies eliminated, there were in all 7 mining companies with an authorized bonded indebtedness aggregating $2,525,000, of which bonds to the value of $1,353,250 had been issued. One of these companies reported $200,000 as authorized but none issued; 4 reported an authorized indebtedness of $1,265,000, of which $1,220,000 was issued. The interest paid amounted to $63,200, the average rate being 5.2 per cent; 2 companies paid no interest on outstanding bonds during the year.

Few companies in the lead-zinc mining industry levied assessments. In 1902, 12 companies, 11 in Missouri and 1 in Wisconsin, reported total assessments since organization amounting to $79,531.

Of the 159 incorporated companies, only 45 declared dividends in 1902. Of this number, 3 companies operated smelting and other manufacturing establishments in connection with their mines, and their reported capitalization and dividends embraced their entire operations. The following table shows the capitalization and dividends of the 42 mining companies by which dividends were paid in 1902, exclusive of the 3 engaged in other business beside mining, and also the capitalization of the 114 companies by which no dividends were declared in 1902.

TABLE 7.—INCORPORATED COMPANIES, DIVIDEND AND NONDIVIDEND PAYING, BY KIND OF STOCK: 1902.[1]

CLASS.	AUTHORIZED.			ISSUED.			Dividends or interest paid.
	Number of shares or bonds.	Par value.		Number of shares or bonds.	Par value.		
		Total.	Average per share or bond.		Total	Average per share or bond.	
Dividend paying companies:							
Total		$17,257,000			$11,458,550		$672,515
Common stock	2,447,350	14,757,000	$6.03	1,490,955	9,808,400	$6.58	618,975
Preferred stock	89,000	2,300,000	25.84	63,768	1,650,150	25.88	53,540
Bonds	400	200,000	500.00				
Companies paying no dividends in 1902:							
Total		28,191,200			21,568,341		63,200
Common stock	5,684,642	25,123,200	4.42	4,497,571	19,492,886	4.33	
Preferred stock	181,800	743,000	4.09	161,005	722,205	4.49	
Bonds	4,690	2,325,000	495.74	2,670	1,353,250	506.84	63,200

[1] Exclusive of 3 companies engaged in manufacturing as well as mining.

Of the 42 dividend paying companies whose dividends are shown in the preceding table, there were only 5 with both preferred and common stock; of these only 1 company declared dividends on both classes of stock, while 4 paid dividends on preferred stock alone. The average rate of dividends on preferred stock was 3.2 per cent. The 38 companies which declared dividends on common stock had an authorized capitalization of $11,957,000, divided into $10,957,000 common, and $1,000,000 preferred; of this the amount outstanding was $6,008,400 common and $425,550 preferred. The average rate of dividends paid by these companies on their common stock was 10.3 per cent.

The census returns furnish no data for determining the net profits earned in mining, since the excess of the value of the product over the expenses reported is not an indication of actual profit; yet some data bearing indirectly on the subject are found in the returns of the dividend paying companies. The payment of dividends by a company may ordinarily be taken as a proof of successful operation. Certainly it must not be assumed that the dividends paid during one year are derived from the profits of the same year, nor that the failure to declare a dividend during a certain year is an evidence of unprofitable mining. In the first case, the dividends may represent the accumulated earnings of former years, while in the second, the surplus may have been invested in the acquisition of new property, in the erection of new plants, etc. With these qualifications, the following comparative summary is presented:

TABLE 8.—*Summary for dividend paying and nondividend paying companies: 1902.*

	Incorporated companies.[1]	Dividend paying companies.	Nondividend paying companies.
Number of companies	156	42	114
Salaries	$594,016	$233,181	$360,835
Wages	$2,713,993	$951,865	$1,762,128
Contract work	$49,103	$21,377	$27,726
Work on share of product	$189,597	$189,597	
Royalties	$507,954	$273,119	$234,835
Miscellaneous expenses, exclusive of royalties	$495,809	$87,489	$408,320
Cost of supplies and materials	$1,612,098	$731,348	$880,750
Value of product	[2]$8,174,181	$3,502,890	[2]$4,671,291
Average value per company	$52,399	$83,402	$40,976
Lead:			
Quantity, short tons	105,085	33,949	71,136
Value	$4,525,081	$1,475,889	$3,049,192
Average value per ton	$43.06	$43.47	$42.86
Zinc:			
Quantity, short tons	124,919	69,453	55,466
Value	$3,633,882	$2,027,001	$1,606,881
Average value per ton	$29.09	$29.19	$28.97

[1] Exclusive of 3 companies engaged in manufacturing as well as mining.
[2] Includes product of custom mills.

It appears from the preceding table that the dividend paying companies enjoyed no advantage either in the grade of their ore or in the marketing of the same, since the average prices received by them did not perceptibly differ from those generally prevailing in 1902. But the two classes differed in the volume of production; the average for dividend paying companies was twice as large as that for the nondividend paying companies, the average being $83,402 and $40,976, respectively.

Employees and wages.—The following table shows the average number of wage-earners employed during each month, by states and territories:

TABLE 9.—*Average number of wage-earners employed during each month, by states and territories: 1902.*

[1] Includes operators as follows: Arizona, 1; Kentucky, 1; New Jersey, 1; New Mexico, 1; New York, 1; Virginia (2 mines; operators reported under iron ore).

The number of salaried officials, clerks, etc., for the 559 mines reporting was 910, or an average of 1.6 to a mine. Of these 76 were salaried officials of corporations. Since the total number of corporations was 161, it appears that more than one-half of them had no salaried officials.

The average number of wage-earners was 7,881, or 14 to a mine. The aggregate wages paid amounted to $4,329,271. Miners working in the mines on shares are not included in the general tables.

In any analysis of these figures it must be borne in mind that the above number of wage-earners is an average computed on the basis of 300 working days, and is not identical with the actual number of persons who earned the amount of wages reported. The average per wage-earner accordingly represents the cost of one man's labor power to the employer, and this cost is not identical with the average annual earnings. For the purpose of estimating the earning capacity of wage-earners, average daily rates should be consulted.

In the following table the distribution of the wage-earners according to daily rates of pay is shown for the various occupations:

TABLE 10.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

RATE PER DAY (DOLLARS).	ALL OCCUPATIONS.		ENGINEERS.		FIREMEN.		MACHINISTS, BLACKSMITHS, CARPENTERS, AND OTHER MECHANICS.		MINERS.		MINERS' HELPERS.		TIMBERMEN AND TRACK LAYERS.		BOYS UNDER 16 YEARS.		ALL OTHER WAGE-EARNERS.

[1] Includes 2 wage-earners paid by the ton, for whom average daily wages are shown.
[2] Less than one-tenth of 1 per cent.

In the above table 6,008 wage-earners, or 76.2 per cent of the total number, are included under the two heads "miners" and "all other wage-earners." It will be noticed also that there is comparatively little difference in the range of wages for the several classes of employees.

Of the total number of wage-earners, 7,196, or 91.3 per cent, received between $1.25 and $2.49 per day. Of those classed as miners the proportion included between those rates was even greater, constituting 95.4 per cent of all the miners. The number of miners who received $1.50 per day was evidently very large, as was also that

of those who were paid $2 per day, for 27.5 per cent are included in the group $1.50 to $1.74 and 36.9 per cent in the group $2 to $2.24.

There were 658 men reported as miners' helpers. The daily rates of pay for 485 of them, 73.7 per cent of the total number, were between $1.25 and $1.74. Only 36 men were reported as timbermen and track layers; the rates of pay for 34 of these men ranged from $1.25 to $2.24. Most of the men employed as firemen received between $1.24 and $2.24 per day; 91.5 per cent of the total number was included between those rates. The rate at which the greatest number were employed was probably $1.50, since 46.4 per cent are included in the group $1.50 to $1.74. For engineers, machinists, and other mechanics wages were somewhat higher. Of the engineers, 93.7 per cent, and of the machinists and other mechanics, 89.3 per cent, were paid between $1.50 and $2.74 per day.

There were 30 boys under 16 years reported as employed in lead and zinc mines, 28 of them from Missouri. Of these boys, 12 were paid between 50 and 74 cents per day, 5 were paid less than 50 cents, while 5 received between 75 and 99 cents, and 8 received $1 or over.

The proportion of the employees included under the head of "all other wage-earners" is very large, but the range of wages differed very little from that for the balance of the wage-earners, 94.1 per cent of the total number having received between $1 and $2.49 per day.

Contract mining, i. e., working at a stated rate per ton, is exceptional in lead-zinc mining; according to the reports a total of $266 was paid for such work during the year, and this amount has been included in the general tables. In those mines, however, where the landowner or first lessee is also the buyer of all ore mined by the sublessees, the latter are virtually wage-earners paid by the ton. The total number of such sublessees reported was 638 and the total amount paid to them was $234,461; out of this amount they were required to furnish their own supplies.

The total number of men engaged in mining can not be ascertained with accuracy. The lead and zinc mine inspector of Missouri reported 11,358 men employed in all capacities at the lead and zinc mines; he explained, however, that "it must not be understood that this number is employed continuously, as quite a number of farmers mine in many counties when not engaged in farm work."[1] The census returns from the lead and zinc mines of Missouri show an average of 6,612 wage-earners and 777 salaried employees, in all 7,389 persons. The average number of the census is the number that would be required at continuous employment for 300 days in the year to produce the quantity of ore reported. The two numbers are incommensurate; the difference between them, 3,969 persons, would be much in excess of the average number of miners working on shares, as well as of the actual number of such miners who at one time or another during the year perform some work in the mines. Taking the value of ore produced as a basis, the average number of such miners could be estimated for Missouri at about 1,300 men.

The following table shows lead and zinc mines classified by the length of time in operation during the year, so far as reports were made in this particular:

[1] Sixteenth Annual Report of the State Lead and Zinc Mine Inspector of Missouri, page 16.

[1] Includes Arizona, 1; Kentucky, 1; New Mexico, 1.

Mechanical power.—Steam was the prevailing kind of power in 1902. There were 1,060 steam engines, 45 electric motors, 32 gas or gasoline engines, 8 water wheels, and 39 other power generators in use during the year. Renting of power was practically unknown; the total number of horsepower supplied to other establishments by the operators reporting was 91, and the total supplied to the mines by other establishments was 199, while a total of 41,901 horsepower was owned. The progress in this respect within the last three decades is shown in the following table, by states and territories:

TABLE 12.—*Steam engines, by states and territories: 1902, 1880, and 1870.*

STATE OR TERRITORY.	1902		1880		1870	
	Number.	Horsepower.	Number.	Horsepower.	Number.	Horsepower.
United States	1,060	38,616	167	6,739	21	953
Illinois	14	364	3	240	1	20
Iowa			1	25	1	40
Kansas	92	2,512	14	268		
Missouri	904	32,953	118	2,805	2	72
Wisconsin	25	617	3	37	4	85
All other states and territories[1]	25	2,170	28	3,364	13	736

[1] Includes the following states and territories: 1902: Arizona, Colorado, New Jersey, New York, and Virginia. 1880: New Jersey, Pennsylvania, and Tennessee. 1870: North Carolina and Pennsylvania.

Production.—In 1902 the dressing of the ore was done at the mine in nearly every case. Of the 559 concerns reporting, 525 were equipped with concentrating plants or hand jigs, 16 were custom mills, and 18 made no report as to equipment for treating the ore, presumably having no facilities for dressing their ore at the mine.

The total reported value of the product of the lead and zinc mines and mills in 1902 was $14,600,177. This amount was made up as shown in the following statement:

Value of the lead and zinc product: 1902.

Production of mines:		
Lead ore	$5,850,721	
Zinc ore	8,665,675	
Total		$14,516,396
Production of custom mills:		
Earned for custom work	34,309	
Ore sold	122,646	
Total	156,955	
Deduct cost of ore purchased	73,174	
Net value		83,781
Total, mines and mills		$14,600,177

While the production of custom mills adds to the value of the ore treated, it can not, theoretically at least, add anything to the quantity of the product; it would therefore be a duplication to add the product of the mills to that of the mines. In actual practice a portion of the product of the custom mills was recovered from "sludge," i. e., mill refuse purchased from the neighboring mines equipped with mills. The reports of the latter are assumed to include the value realized from the sale of sludge; it is, however, by no means certain that these values are included in all cases. The sludge is considered of little value; it is usually sold for a lump sum, without much regard to quantity. It is possible, therefore, that by deducting the value of purchased ore from the total value of the product the value of the lead and zinc product may have been underrated. Likewise, by omitting from the quantity of the product shown in Table 13, the output of custom mills, the total production may have been underrated. Still, as the gross value of all the ore sold by the mills amounted to only $122,646, or less than 1 per cent of the total production of the lead-zinc mines, the error may be treated as a negligible quantity.

The quantity, total value, and average value per ton of lead and zinc ore produced in 1902 are shown by states and territories in the following table:

TABLE 13.—QUANTITY, TOTAL VALUE, AND AVERAGE VALUE PER TON OF LEAD AND ZINC ORE, BY STATES AND TERRITORIES: 1902.

STATE OR TERRITORY.	TOTAL.		LEAD ORE.			ZINC ORE.		
	Value.	Per cent of total.	Short tons.	Value.	Average value per ton.	Short tons.	Value.	Average value per ton.
United States[1]	$14,526,988	100.0	132,330	$5,861,313	$44.29	491,332	$8,665,675	$17.64
Illinois	90,619	0.6	792	30,936	39.06	2,778	59,683	21.48
Iowa	13,358	0.1	186	9,106	48.96	376	4,252	11.31
Kansas	707,026	4.9	3,468	163,084	47.03	21,642	543,942	25.13
Missouri	12,513,021	86.1	124,537	5,520,211	44.33	240,057	6,992,810	29.13
Wisconsin	473,652	3.3	2,623	122,184	46.58	19,376	351,468	18.14
All other states and territories[2]	729,312	5.0	724	15,792	21.81	207,103	713,520	3.45

[1] Does not include the production of custom mills in Kansas and Missouri.
[2] Includes the following states and territories: Arizona, Colorado, Kentucky, New Jersey, New Mexico, New York, and Virginia.

The value of the lead and zinc ores shown in the preceding table is $14,526,988, or $73,189 less than the value of product shown in Table 1, and in the detailed summary. This difference is accounted for by the absence of the net value of the production of custom mills in Kansas and Missouri. According to the preceding table, six-sevenths of the lead and zinc production of the United States was furnished by the state of Missouri.

The progress made by the lead-zinc mining industry

since the Eleventh Census appears from the following comparative summaries:

TABLE 14.—*Comparative summary, quantity and value of lead ore, by states and territories: 1902 and 1889.*

STATE OR TERRITORY.	SHORT TONS.			VALUE.		
	1902	1889	Per cent of increase.	1902	1889	Per cent of increase.
United States[1]	132,330	50,238	163.4	$5,861,313	$1,754,380	234.1
Missouri	124,537	44,482	180.0	5,520,211	1,571,161	251.4
Kansas	3,468	3,617	[2] 4.1	163,084	103,236	58.0

[1] Does not include the production of custom mills in Kansas and Missouri in 1902.
[2] Decrease.
[3] Includes New Jersey and Virginia.
[4] Includes New Jersey and Pennsylvania. Number not reported.
[5] Includes Colorado, Kentucky, and New Mexico.
[6] Includes Arkansas, New Mexico, and the Southern states.

In the following statement the census returns for Missouri are compared with the report of the lead and zinc mine inspector of that state:

Quantity and value of lead and zinc ore, Census and Missouri mine inspector's returns: 1902.

SOURCE OF INFORMATION.	Total value.	LEAD ORE.			ZINC ORE.		
		Short tons.	Value.	Average value per ton.	Short tons.	Value.	Average value per ton.
Census returns[1]	$12,513,021	124,537	$5,520,211	$44.33	240,057	$6,992,810	$29.13
State mine inspector's returns	12,370,985	126,831	5,318,157	41.93	234,903	7,052,828	30.02
Difference:							
More (+) or less (−)	−142,036	+2,294	−202.054	−2.40	−5,154	+60,018	+0.89
Per cent	-1.1	+1.8	−3.7	-5.4	- 2.1	+0.8	+3.0

[1] Exclusive of production of custom mills.

As evidenced by the preceding statement, the census returns on production are in substantial agreement with those of the state mine inspector. Small discrepancies of from 1 to 3 per cent are quite unavoidable in view of the nature of the information. In many cases the value reported by the operator was not the actual amount entered on his books, but an estimate based upon an assumed average value of the ore, which was the best information obtainable. Small operators only too often keep very imperfect books, if any, whereas the largest producers, who do not sell their ores but smelt them at their own plants and market the bullion, must put an assumed valuation upon the ore in order to answer the inquiries of the Bureau of the Census or of the state bureau of mines. Therefore, if the reports of such operators were made on different dates, the estimates for the same mining company might differ, and in more than one case this state of affairs was disclosed by a comparison of the confidential census returns with the figures published by the state mine inspector. That the discrepancy is on the whole within such narrow limits may be accepted as proof of the substantial accuracy of the returns.

The mining district comprising Kansas and a portion of Missouri is called the Joplin-Galena district. The average base prices of zinc and lead ores in this district, computed from monthly averages for 1902, were reported by the United States Geological Survey as follows: Lead per 1,000 pounds, $23.05; zinc per short ton, $30.33. For 1902 the range of fluctuations of monthly base prices in the same district was as follows:

	Lead ore per 1,000 pounds.	Zinc ore per short ton.
Highest price	$25.00	$34.37
Lowest price	21.00	26.76
Variation	4.00	7.61

These averages are not strictly comparable with the average values by states and territories given in Table 13. The variations, however, are inconsiderable, viz:

Average value above (+) or below (−) base price.

	Lead ore per 1,000 pounds.	Zinc ore per short ton.
Kansas	−$0.46	+$5.20
Missouri	− 0.89	+ 1.20

It appears from these comparisons that the variations between the values reported to the Bureau of the Census and the average base prices for the year 1902 were within the ordinary range of market fluctuations. The quantity reported represents dressed ore of various grades, except in a few cases where the quantity of rough ore was reported and could not be reduced to terms of dressed ore.

Table 16 is a summary of the statistics for all lead and zinc mines in Missouri at the censuses of 1902, 1880, and 1870.

TABLE 16.—*Comparative summary, lead and zinc mines, Missouri: 1902, 1880, and 1870.*

	1902	1880	1870
Number of mines	374	71	42
Number of operators	374	71	42
Salaried officials, clerks, etc.:			
Number	777	342	(1)
Salaries	$727,021	(2)	(1)
Wage-earners:			
Average number	6,612	4,180	539
Wages	$3,691,923	[2]$2,034,254	$124,179
Contract work	$105,877	(1)	(1)
Miscellaneous expenses	$1,768,458	(1)	(1)
Cost of supplies and materials	$2,189,461	$194,532	$5,654
Value of product	$12,555,580	$2,077,944	$201,885

[1] Not reported. [2] Salaries included in wages.

As has been stated above, at the Eleventh Census the statistics of zinc mines of southern Missouri were confined to the quantity and value of the output. Mine expenses were reported only for lead mines. In the following table the data concerning these mines are collated with the expenses and production of the mines for which the product reported for 1902 was likewise only lead ore:

TABLE 17.—*Comparative summary of mines producing lead ore only, Missouri: 1902 and 1889.*

	1902	1889
Number of mines	59	(1)
Salaries	$308,290	(1)
Wages	$1,448,902	$401,431
Contract work	$30,031	$8,525
Miscellaneous expenses	$465,212	$142,153
Cost of supplies and materials	$842,945	$244,784
Product:		
Short tons	93,926	44,482
Value	$4,126,278	$1,571,161

[1] Not reported.

The following table, reproduced from the report of the state lead and zinc mine inspector of Missouri for 1902, shows the growth of the zinc production in that state, by years, from the beginning of zinc mining, in 1873, to the year 1902. The output of 1902, as reported by the state mine inspector, exceeds by eight-tenths of 1 per cent that reported to the Bureau of the Census. The reasons for this insignificant variance are discussed on a previous page.

TABLE 18.—*Quantity and value of zinc ore, Missouri: 1873 to 1902.*

[Sixteenth Annual Report of the Lead and Zinc Mine Inspector of Missouri, for the year ending December 31, 1902.]

YEAR.	Number of tons.	Amount received for output.	YEAR.	Number of tons.	Amount received for output.

1889	82,357	1,765,734.08			

[1] For ten years prior to 1901 the above figures covered a fiscal year ending June 30. The six months accounted for above are the last six months of 1900, making full years for the period.

LEAD CONTENTS OF LEAD AND ZINC ORES.

The lead contents of the ore can be estimated by comparison with the returns from lead smelters. The returns from 5 leading mining and smelting companies of Missouri show a total of 103,428 tons of their own and purchased ore treated, from which 70,491 tons of lead were recovered, or an average of 68.2 per cent. The quantity of nonargentiferous lead ore treated by those companies is equal to 78 per cent of the total quantity mined during the year. A glance at the price column of Table 13 shows that the ore was brought by concentration to about the same grade throughout the nonargentiferous lead region. The only exception is found in the group of "all other states," where the quantity reported apparently represented crude ore. The quantity, however, being only somewhat over two-tenths of 1 per cent, the effect of this variation upon the average for the United States could not exceed a few cents per ton. The average percentage of recovery reported by the above-mentioned 5 smelting companies—viz, 68 per cent—may therefore be taken as representative of the results generally obtained in the United States.[1] The metal yield of all nonargentiferous ores may be estimated on this basis, in round figures, at 90,000 tons. According to reports from the same companies, lead bullion of the value of $2,534,683 was produced from concentrates valued at $2,045,978—i. e., 24 per cent was added to the value of concentrates by smelting. The total reported value of the lead concentrates produced in the United States was $5,850,721. By an addition of 24 per cent of this amount $7,255,000 is obtained as the estimated value of the 90,000 tons of metallic lead

[1] The relation of the product to lead ores consumed in 1880 was represented by the following percentages: Illinois, 68.6; Iowa, 70.2; Wisconsin, 66.6; Kansas, 69.3; and Missouri, 72.4.

recoverable from nonargentiferous ores. The average value is 4.03 cents per pound of refined lead, which is within the range of the prices of lead at New York city in 1902 as reported by the United States Geological Survey—viz, highest, 4.10 cents; lowest, 4 cents. The reports made by smelters to the United States Geological Survey show 79,445 tons of pig lead produced from nonargentiferous ores of Missouri, Kansas, Wisconsin, Illinois, Iowa, Virginia, and Kentucky. The difference is accounted for by the fact that "a considerable quantity of the ore is converted into a pigment."[1]

ZINC CONTENTS OF LEAD AND ZINC ORES.

The zinc ores of Missouri and Kansas are usually sold upon an assay basis of 60 per cent of metallic zinc in the concentrates, with a deduction of $1 for every unit or percentage below that standard, and a similar allowance for higher grades of concentrates. Sixty per cent is thought to be, approximately, the average for the entire district.

The price of ore shipped from mines in Wisconsin is determined by the price of ore in Missouri. The average value per ton of zinc ore in Missouri was $29.13, and in Wisconsin $18.14; the difference, $10.99, may be taken as reflecting the difference in the grade of the concentrates, and would show an average assay of 49 per cent for Wisconsin ore (dressed). The three states named furnished 278,727 tons out of a total of 283,680 tons for the Western states, or 98.3 per cent of the total output of western mines. The eastern and southern ores are of a much lower grade. The average zinc contents of New Jersey concentrates was about 25 per cent; the chemical composition of the ore, according to Mr. Ingalls, is 23.58 per cent zinc. The concentrates of Virginia assay 38.08 zinc.[2] From these data the zinc contents of the ores mined are estimated for the principal producing states as follows:

TABLE 19.—*Zinc contents of ores mined in the principal producing states: 1902.*

STATE.	Short tons of concentrates.	Average assay (per cent).	Zinc contents (short tons).
Total	482,607	.....	217,726
Missouri	240,057	60	144,034
Kansas	21,642	60	12,985
Wisconsin	19,376	49	9,494
New Jersey[1]	201,532	25	51,213
Virginia[1]		38	

[1] The computation is made separately for New Jersey and Virginia, but the returns can not be shown separately without disclosing individual operations.

This leaves 8,725 tons of ore, or about 2 per cent, the zinc contents of which are a matter of conjecture.

GENERAL SUMMARY OF LEAD AND ZINC MINES, BY STATES AND CHARACTER OF MINE.

A table for all lead and zinc mines is presented by states. Small mines from which no individual reports were received are not included in this statement. The royalties shown in the detailed summary at the close of this report include those paid by these sublessees; therefore royalties are omitted also. The rate of royalty is fixed by custom and does not, as a rule, vary in individual cases. Custom mills which merely rework ore mined elsewhere or mill refuse ("sludge") are not included in the following table which is intended to present the facts relating to mines only:

[1] United States Geological Survey, "Mineral Resources of the United States," 1902, page 209.

[2] Production and Properties of Zinc, by Walter Renton Ingalls, pages 193 and 201.

TABLE 20.—SUMMARY OF LEAD AND ZINC MINES, BY STATES: 1902.

STATE.	Number of mines.	Salaries.	Wages.	Contract work.	Work on share of product.	Miscellaneous expenses, exclusive of royalties.	Cost of supplies and materials.	Value of product.
United States[1]	541	$818,451	$4,244,256	$108,607	$244,661	$543,172	$2,058,933	$12,550,617
Illinois	14	9,120	51,565	.....	.....	1,226	20,464	90,619
Iowa	14	280	5,766	.....	.....	556	919	13,358

Missouri	362	721,905	3,650,337	105,877	228,664	512,996	1,748,749	10,963,294
Wisconsin	90	26,202	192,209	1,008	.....	1,658	56,774	473,652
All other states[2]	7	40,161	214,795	800	15,997	16,510	159,574	666,751

[1] Custom mills and small mines not included.
[2] Includes operators distributed as follows: Colorado, 3; New Jersey, 1; New York, 1; Virginia, 2.

In analyzing the figures of the preceding table, the prevalence of mining on a small scale in Iowa and Wisconsin should be taken into consideration. In a mine worked on a small scale the operator gives his personal attention to many details of business which on a larger scale of operation require the services of salaried employees; furthermore, the absence of steampower in the great majority of these mines reduced the expense for supplies.

Where the same mine produces both lead and zinc ore, it is impossible to segregate the expenses incident to each of these products. There were a number of mines, however, which reported but one product, either lead or zinc ore.

The following is a comparative summary of all mines, classified according to the character of their product, the division showing those producing lead ore only, those producing zinc ore only, and those producing both lead and zinc ore:

TABLE 21.—SUMMARY OF MINES, BY CHARACTER OF PRODUCT: 1902.

CHARACTER OF PRODUCT.	Number of mines.	Salaries.	Wages.	Contract work.	Work on share of product.	Miscellaneous expenses, exclusive of royalties.	Cost of supplies and materials.	Value of product.	LEAD.			ZINC.		
									Short tons.	Value.	Value per ton.	Short tons.	Value.	Value per ton.
United States[1]	541	$818,451	$4,244,256	$108,607	$244,661	$543,172	$2,058,933	$12,550,617	122,307	$5,418,490	$44.30	430,647	$7,132,127	$16.56
Lead ore	108	314,875	1,493,068	30,031	27,139	384,715	855,514	4,209,174	95,790	4,209,174	43.94	.....	.....	.....
Zinc ore	144	171,792	844,233	12,792	.....	67,014	590,756	2,467,623	.....	.....	.....	263,985	2,467,623	9.35
Lead and zinc ore	289	331,784	1,906,955	65,784	217,522	91,443	612,663	5,873,820	26,517	1,209,316	45.61	166,662	4,664,504	27.99

[1] Custom mills and small mines not included.

The average value realized per ton of lead ore shows no marked difference for either class of lead mines. The average values per ton of zinc ore, shown in the preceding table, are misleading because they include the low grade zinc ores of New Jersey and Virginia. When those ores are eliminated, the total output of distinctively zinc mines is reduced to 62,453 tons, valued at $1,824,470, which corresponds to an average value of $29 per ton. Thus there is no perceptible difference in the average value of zinc ore of the same class.

The following is a comparative summary of zinc mines by districts, viz, Kansas and Missouri, which is the main zinc producing region; the upper Mississippi valley, extending over Wisconsin, Illinois, and Iowa; and the Eastern states, embracing New Jersey and Virginia:

TABLE 22.—SUMMARY FOR MINES PRODUCING ZINC ORE EXCLUSIVELY, BY DISTRICTS: 1902.

DISTRICT.	Number of mines.	Salaries.	Wages.	Contract work.	Miscellaneous expenses, exclusive of royalties.	Cost of supplies and materials.	PRODUCT.		
							Short tons.	Value.	Average per ton.
United States	144	$171,792	$844,233	$12,792	$67,014	$590,756	263,985	$2,467,623	.....
Kansas and Missouri	113	125,544	572,652	11,965	50,287	414,216	56,236	1,702,829	$30.28
Upper Mississippi valley[1]	28	8,312	62,821	827	747	19,966	6,217	121,641	19.57
Eastern states[2]	3	37,936	208,760	.....	15,980	156,574	201,532	643,153	3.19

[1] Includes mines as follows: Illinois, 3; Iowa, 2; Wisconsin, 23.

[2] Includes mines as follows: New Jersey, 1; Virginia, 2.

The following table is a summary for lead mines yielding no zinc by product, by districts:

TABLE 23.—SUMMARY FOR MINES PRODUCING LEAD ORE EXCLUSIVELY, BY DISTRICTS: 1902.

DISTRICT.	Number of mines.	Salaries.	Wages.	Contract work and work on share of product.	Miscellaneous expenses, exclusive of royalties.	Cost of supplies and materials.	PRODUCT.		
							Short tons.	Value.	Average per ton.
United States	108	$314,875	$1,493,068	$57,170	$384,715	$855,514	95,790	$4,209,174	$43.94
Missouri	59	308,290	1,448,902	57,170	383,380	842,945	93,926	4,126,278	43.93
Upper Mississippi valley[1]	49	6,585	44,166	.....	1,335	12,569	1,864	82,896	44.47

[1] Includes mines distributed as follows: Illinois, 10; Iowa, 12; Wisconsin, 27.

A detailed summary of the lead and zinc ore industry for 1902 is given in Table 34.

AURIFEROUS AND ARGENTIFEROUS LEAD AND ZINC ORES.

The statistics of mines producing auriferous and argentiferous lead and zinc ores are given in the report on gold and silver. Still, as these ores furnish a not inconsiderable share of the materials from which lead and zinc are produced in this country, a proper comparison of the production of the mines with the consumption of the lead and zinc ores must embrace all classes of these ores. The production of lead and zinc from all sources, as returned by the census of mines and quarries for the year 1902, is collated in the following statement:

Value of lead and zinc in all ores, by sources of production: 1902.

	Lead.	Zinc.
Total	$18,181,013	$9,006,361
In nonargentiferous lead and zinc ores	5,850,721	8,665,675
In gold and silver ore	12,311,239	340,686
In copper ore	19,053	.....

Mr. Harry A. Lee, commissioner of mines of Colorado, in his report for 1901–2, wrote as follows of zinc mining in that state:

> Zinc is practically a new product that occurs intimately associated with iron and lead sulphides in bodies of great magnitude. Until within the past few years these ore bodies were worthless on account of the zinc sulphides present, and were, therefore, as far as possible, left intact in the mines. The extraction of the more valuable ores has, nevertheless, developed large bodies of zinciferous ores that are now a valuable asset.[1]

Zinc associated with gold, silver, and lead was reported from Colorado, where, according to census returns, 51,996,073 pounds of zinc were contained in 245,555 tons of gold and silver bearing lead ore, showing an average assay of 10.6 per cent of zinc in the ore. In addition to this, the reports from nonargentiferous lead and zinc mines included in the preceding statements show a product of 1,536 tons of zinc concentrates. The commissioner of mines estimated the production for 1902 at 52,582,510 pounds of zinc. This leaves 586,437 pounds for the contents of 1,536 tons of nonargentiferous lead and zinc ore included in previous statements, which would correspond to 19.5 per cent of zinc in the dressed ore. The estimate is apparently too low.

The value reported to the Bureau of the Census is $335,436 for the zinc contents of argentiferous ore and $18,398 for the lead and zinc ores; in all, $353,834. The value reported by the commissioner of mines was computed at the average price for spelter, 4.84 cents per pound, which amounts to $2,544,993. The price realized by the mine operator was about 13.9 per cent of the value of metallic zinc contained in the ore.

The mineralogical character of the zinc bearing ores of Colorado is shown in the following statement:

[1] Report of the State Bureau of Mines of Colorado for the years 1901–2, page 105.

Assay contents of the zinc ores of Colorado: 1902.

CLASS OF ORE.	Number of mines reporting.	Gold value.	Silver value.	LEAD.		ZINC.	
				Pounds.	Value.	Pounds.	Value.
Total	12	$139,619	$633,064	11,316,284	$260,412	51,996,072	$335,436
Associated with gold and silver	2	540	1,937			574,753	5,260
Associated with gold, silver, and lead	7	139,079	616,875	9,290,784	230,206	47,395,139	295,796
Associated with silver and lead	3		14,252	2,025,500	30,206	4,026,180	34,380

A classification of these zinc bearing ores by the commercial value of the principal metal is presented in the following statement:

Classification of zinc bearing ores of Colorado by the commercial value of the principal metals: 1902.

COMPOSITION OF THE ORE.		Value of zinc contents.
Metals of chief value.	Other metals.	
Total		$335,436
Gold and silver	Lead	150,734
Lead	Gold and silver	45,562
Zinc	Lead, gold, and silver	139,140

As appears from the preceding statement, most of the Colorado zinc was a by-product of auriferous and argentiferous lead ore. Lead smelters very reluctantly handle this class of ore; they make no allowance for the zinc, and even charge a penalty in case the assay shows zinc in excess of a certain percentage. According to Census reports, concentration and magnetic separation of zinc ore have been introduced at some mines. Shipments of zinc ore were made to Kansas zinc smelters and to New York for export. Under the stimulus of the growing supply of zinc ore, zinc works have been recently erected in Colorado.

Reports from Utah show 19,582,443 pounds of zinc among the contents of argentiferous lead ore. With the exception of a small shipment assaying 105,000 pounds of zinc, no returns were brought by the zinc, although the rough ore assayed 4.2 per cent zinc. The ore was bought by lead smelters for its gold, silver, and lead contents. In Utah as well as in Colorado there were other mines which produced zinciferous ores; but since the operators received no returns for their zinc, they kept no records of the same, and failed to report it to the Bureau of the Census.

Consumption of zinc ore.—The zinc contents of lead and zinc ore were estimated above at 217,726 tons, exclusive of the contents of 8,725 tons, which could not be estimated with any degree of accuracy. The zinc contents of auriferous and argentiferous ores were given in Census reports from Colorado as 25,998 tons. The reports from Utah showed one shipment of ore assaying 52 tons of zinc, for which payment was received. This makes a total of 243,776 tons of zinc and 8,725 tons of zinc ore. No account is taken of zinciferous ore shipped to lead smelters, there being no positive information to show how the zinc contents of such ores were utilized, or even that they were utilized at all.

The production of spelter for 1902 was reported by the United States Geological Survey as 156,927 tons. Allowing 15 per cent for the loss in smelting, the zinc contents of the ores from which this output was extracted, may be estimated at 184,600 tons. To this must be added the output of zinc oxide, which is manufactured in the United States directly from the ore. The production of zinc oxide for 1902 is estimated[1] at 52,730 tons. The zinc contents of this product, figured at the rate of 80.3 per cent of zinc in the oxide, were equal to 42,342 tons. The total output of zinc in all

[1] The Mineral Industry, Vol. XI, page 600.

forms for 1902 may be estimated therefore at 226,942 tons, or in round numbers at 227,000 tons.

The exports of zinc ore for the calendar year 1902 were 49,762 long tons,[1] or 55,733 short tons. Of this quantity, 20,883 long tons were exported through New York; the rest, with the exception of a small quantity, was exported through Galveston. The New York exports represented New Jersey ores which contained, at an assay rate of about 25 per cent, 5,221 long tons or 5,847 short tons of zinc. The estimated production and consumption would thus compare as follows:

Production and consumption of zinc: 1902.

	Zinc (short tons).	Ore (short tons).
Total production	243,776	8,725
Domestic consumption in the manufacture of spelter and oxides	227,000	.....
Exports:		
New Jersey ores	5,847	.....
Other ores[1]	.....	32,344
Total consumption	232,847	32,344
Excess (+) or deficiency (−) of production over consumption	+10,929	−23,619

[1] 28,879 long tons.

The deficiency of 23,619 tons of ore in the preceding calculation is covered by the excess of 10,929 tons of zinc, which corresponds to an average tenor of 46 per cent zinc in western ores. No account is taken here of the increase or decrease of the stock of ore. It must be understood that these are only rough estimates, allowing a wide range for error.

Tendency toward centralization.—The lead-zinc mining industry has not escaped the general trend of modern business toward centralization. In this respect a marked difference in degree exists between those mines which may be classed as zinc mines, lead being mined only as a by-product, and those which may properly be classed as lead mines, zinc occurring, if at all, as a by-product.

The following table shows the distribution of lead mines by value of production in 1902:

[1] United States Geological Survey, "Mineral Resources of the United States," 1902, page 225.

TABLE 24.—*Classification of lead mines by value of product: 1902.*[1]

PRODUCT PER MINE.	Number of mines.	VALUE OF PRODUCT. Total.	Per cent of total.	Lead.	Zinc.
Total[2]	176	$4,963,625	100.0	$4,743,264	$220,361
Less than $500	45	9,335	0.2	8,777	558
$500 to $999	23	17,784	0.4	15,848	1,936
$1,000 to $9,999	66	210,540	4.2	181,378	29,162
$10,000 to $49,999	29	595,892	12.0	484,236	111,656
$50,000 to $99,999	5	381,737	7.7	304,688	77,049
$100,000 to $499,999	5	1,250,719	25.2	1,250,719	.....
$500,000 and over	3	2,497,618	50.3	2,497,618	.....

[1] A classification by states is impossible without disclosing the identity of some individual establishments.
[2] Custom mills and small mines not included.

The following table shows the zinc mines classified by value of production:

TABLE 25.—*Classification of zinc mines by value of product: 1902.*[1]

PRODUCT PER MINE.	Number of mines.	VALUE OF PRODUCT. Total.	Per cent of total.	Zinc.	Lead.
Total[2]	365	$7,586,992	100.0	$6,912,030	$674,962
Less than $500	26	6,305	0.1	6,020	285
$500 to $999	28	19,586	0.2	17,908	1,678
$1,000 to $9,999	150	629,497	8.3	552,228	77,269
$10,000 to $49,999	118	3,050,173	40.2	2,751,249	298,924
$50,000 to $99,999	36	2,372,151	31.3	2,177,674	194,477
$100,000 and over[3]	7	1,509,280	19.9	1,406,951	102,329

[1] A classification by states is impossible without disclosing the identity of some individual establishments.
[2] Custom mills and small mines not included.
[3] Includes 1 establishment reporting a product of over $250,000 but less than $500,000, and 1 reporting a product of over $500,000.

Missouri.—The state lead and zinc mine inspector of Missouri, in his report for 1902, noted the decrease within recent years of the number of individual operators, who were giving place to large and strong companies.[2] As the mines of Missouri furnish the bulk of the zinc and soft lead production of the United States, the tendencies observed in Missouri may be said to be representative of the industry in general.

In soft lead mining the progress of centralization is far in advance of that manifested by the zinc mining industry. The degree of centralization reached in each branch appears from Tables 26 and 27, which show the distribution of all operators by value of production. This classification does not include the great number of sublessees employing no hired labor.

[2] Sixteenth Annual Report of the State Lead and Zinc Mine Inspector of Missouri, pages 10 and 11.

TABLE 26.—*Classification of lead mines, Missouri, by value of product: 1902.*[1]

PRODUCT PER MINE.	Number of mines.	VALUE OF PRODUCT. Total.	Percentage of total.	Lead.	Zinc.
Total	108	$4,788,799	100.0	$4,596,606	$192,193
Less than $500	20	3,643	0.1	3,190	453
$500 to $999	15	11,248	0.2	9,888	1,360

$10,000 to $49,999	23	516,814	10.8	426,464	90,350
$50,000 to $99,999	5	381,737	8.0	304,688	77,049
$100,000 to $499,999	5	1,250,719	26.1	1,250,719	.....
$500,000 and over	3	2,497,618	52.2	2,497,618	.....

[1] Exclusive of the production of sublessees who employ no hired labor.

TABLE 27.—*Classification of zinc mines, Missouri, by value of product: 1902.*[1]

PRODUCT PER MINE.	Number of mines.	VALUE OF PRODUCT.			
		Total.	Per cent of total.	Zinc.	Lead.
Total	254	$6,174,495	100.0	$5,587,181	$587,314
Less than $500	19	4,486	0.1	4,222	264
$500 to $999	15	11,197	0.2	10,523	674
$1,000 to $9,999	82	366,072	5.9	326,533	39,539
$10,000 to $49,999	98	2,600,174	42.1	2,343,122	257,052
$50,000 to $99,999	34	2,266,991	36.7	2,079,535	187,456
$100,000 and over[2]	6	925,575	15.0	823,246	102,329

[1] Exclusive of the production of sublessees who employ no hired labor.
[2] Includes 1 establishment reporting a product of over $250,000.

It is apparent from the preceding tables that the bulk of the zinc mine output of Missouri is the result of production on a middle scale, or from $10,000 to $100,000; very large producers, as well as the very small, falling far behind, while over three-quarters of the output of soft lead is furnished by 8 mines, with a production of more than $100,000 each. Three operators, each with an output exceeding $500,000, produced over one-half of the lead output of the state.

Tables 28 and 29, showing the correlation between the value of production and ownership of mineral lands, have been compiled in this office from the individual reports of mining companies published in the annual report of the lead and zinc mine inspector of the state of Missouri for the year 1902.

TABLE 28.—LEAD MINES OF MISSOURI, ACREAGE OWNED, AND VALUE OF PRODUCT: 1902.

[Compiled from 16th Annual Report of the State Lead and Zinc Mine Inspector of Missouri.]

SIZE OF PROPERTY.	Number of owners.	ACREAGE.		VALUE OF PRODUCT.				
		Total.	Per cent of total.	Total.	Per cent of total.	Per acre.	Lead.	Zinc.
Total[1]	45	90,519	100.0	$4,409,044	100.0	$49	$4,216,692	$192,352
Less than 10 acres	4	19	(2)	11,927	0.3	628	10,064	1,863
10 to 99 acres	18	800	0.9	399,048	9.0	499	253,699	145,349
100 to 999 acres	11	4,282	4.7	504,308	11.4	118	459,168	45,140
1,000 acres and over	12	85,418	94.4	3,493,761	79.3	41	3,493,761	.....

[1] Exclusive of lead valued at $117,374 and zinc at $420, produced by operators who did not report acreage.
[2] Less than one-tenth of 1 per cent.

As appears from the preceding table, the title to all lead bearing lands in Missouri were concentrated in the hands of 45 owners, 94 per cent of all the lands being held by 12 owners in tracts of over 1,000 acres. The same properties furnished over three-fourths (77.74 per cent) of the total production. The production per acre decreased with the increase of the acreage, the range being from $628 per acre for the small properties to $41 per acre for the larger ones; this points to the fact that the larger properties are as yet undeveloped.

TABLE 29.—ZINC MINES OF MISSOURI, ACREAGE OWNED, AND VALUE OF PRODUCT: 1902.

[Compiled from 16th Annual Report of the State Lead and Zinc Mine Inspector of Missouri.]

SIZE OF PROPERTY.	Number of owners.	ACREAGE.		VALUE OF PRODUCT.				
		Total.	Per cent of total.	Total.	Per cent of total.	Per acre.	Zinc.	Lead.
Total[1]	147	35,248	100.0	$7,630,402	100.0	$216	$6,685,875	$944,527
Less than 10 acres	17	85	0.2	230,415	3.0	2,711	215,885	14,530
10 to 99 acres	99	4,148	11.8	3,415,367	44.8	823	3,067,548	347,819
100 to 999 acres	25	6,191	17.6	2,625,250	34.4	424	2,271,784	353,466
1,000 acres and over	6	24,824	70.4	1,359,370	17.8	55	1,130,658	228,712

[1] Exclusive of zinc valued at $174,181 and lead valued at $39,564, produced by operators who did not report acreage.

As appears from the above table, over two-thirds of all the zinc bearing lands were owned by 6 companies. The output, however, did not keep pace with the area owned, since only one-sixth of the total output was produced by these 6 companies. With the increase in the size of the property there was a decrease in the production per acre; while the small properties yielded $2,711 per acre, the largest yielded only $55 per acre. This indicates that the greater part of the extensive zinc bearing fields owned by the larger companies is still awaiting development, whereas the small properties are under active operation.

Local observers have noted the connection between the growth of centralization and the progress of deep mining. Shallow mining, which was universal in the past, has given way to deep mining, as shown in the following table compiled from the Report of the State Lead and Zinc Mine Inspector of Missouri:

TABLE 30.—*Depth of shaft and value of product in Missouri: 1902.*

[Compiled from 16th Annual Report of the State Lead and Zinc Mine Inspector of Missouri.]

AVERAGE DEPTH OF SHAFT.	Number of operators or lessees.	VALUE OF PRODUCT. Total.	Per cent of total.	Average per operator.
Total [1]	189	$11,937,186	100.0	$66,688
Less than 100 feet	35	428,520	3.6	12,243
100 to 199 feet	124	6,812,629	57.1	54,940
200 feet and over	30	4,696,037	39.3	156,535

[1] Exclusive of lead and zinc valued at $433,799, produced from mines that did not report the depth of shaft.

It appears from this table that the bulk of the product was obtained from mines over 100 feet in depth; about two-fifths of the production came from mines over 200 feet in depth. The average value per operator increased with the depth of the mine.

Production on a small scale.—There were in 1902 a number of mines operated by means of animal or hand power only. The Report of the State Mine Inspector of Missouri shows that there were in that state 857 shafts equipped with 639 steam hoisters and 265 horse hoisters. Of the 559 mines and mills reported to the Bureau of the Census, 170 were without mechanical power, 355 possessed mechanical power, 16 were custom mills, and 18 failed to report as to their equipment.

Table 31 shows the average production for all mines and for those using hand and animal power only, by states.

TABLE 31.—*Average production for all mines and for those using hand and animal power only, by states: 1902.*

STATE.	AVERAGE VALUE OF PRODUCT PER MINE. All mines.	With hand and animal power only.
United States	$23,199	$2,852
Illinois	6,473	3,897
Iowa	954	1,726
Kansas	6,351	2,557
Missouri	30,285	2,476
Wisconsin	5,263	3,375

The following table shows the distribution of the mines using only hand and animal power, by value of production, and by states:

TABLE 32.—*Number and value of production of mines without mechanical power, by states: 1902.*

PRODUCT PER MINE.	NUMBER OF MINES. United States.	Kansas.	Missouri.	Wisconsin.	All other states.[1]
Total	170	20	58	73	19
Less than $500	48	4	20	17	7
$500 to $999	28	4	12	10	2
$1,000 to $9,999	82	11	21	42	8
$10,000 to $49,999	12	1	5	4	2

[1] Includes Illinois and Iowa.

Table 33 is a summary showing expenses and product, by states, for mines using hand and animal power only.

TABLE 33.—SUMMARY FOR MINES OPERATED WITHOUT MECHANICAL POWER, BY STATES: 1902.

STATE.	Number of mines.	Number of owners working.	Salaries.	Wages.	Contract work and work on share of product.	Miscellaneous expenses, exclusive of royalties.	Cost of supplies and materials.	PRODUCT. Total value.	Lead. Short tons.	Lead. Value.	Zinc. Short tons.	Zinc. Value.
United States	170	170	$19,484	$170,354	$29,365	$4,202	$44,087	$484,800	5,015	$236,911	13,543	$247,889
Illinois	5			10,520			1,041	19,486	110	5,406	700	14,080
Iowa	14	14	280	5,766		556	919	24,158	186	9,106	375	15,052
Kansas	20	64	125	9,289			6,609	51,140	543	23,949	903	27,191
Missouri	58	68	9,363	47,104	28,867	2,752	17,183	143,631	2,375	115,603	1,491	28,028
Wisconsin	73	24	9,716	97,675	498	894	18,335	246,385	1,801	82,847	10,074	163,538

A computation from the figures presented shows an average value of about $47 per ton of lead ore. The average computed for all mines of the same states was about $44. The value per ton of zinc ore realized by the operators using only hand and animal power averaged about $18, and the average computed for all mines of the same states was likewise about $18. This shows that in marketing their ores the small operators enjoyed the same facilities as all other competitors in the lead and zinc market.

The detailed statistics of lead and zinc mining for 1902 are given in Table 34.

DESCRIPTIVE.

The earliest discovery of lead on the American continent is recorded fourteen years after the landing of the first English settlers in Virginia. In 1621 lead deposits were found in the vicinity of Falling creek, near Jamestown. The steady tide of European immigration in the seventeenth and eighteenth centuries caused a growing demand for bullets and stimulated further discoveries wherever the settlements of the colonists extended. The French acquainted the northwestern Indians with firearms, inducing them to hunt

fur bearing animals on a large scale; consequently lead assumed a value in the eyes of the Indians, both for use in making bullets for their own weapons and as an article of traffic. Toward the close of the seventeenth century the Indians living in the region comprising portions of the present states of Wisconsin, Illinois, and Iowa, were smelting lead and bartering it with the French traders. In the second half of the eighteenth century lead had become of such importance in the trade of the upper Mississippi country that it served as currency, the rate of exchange being a peck of corn for a peck of ore. In 1810 Nicholas Boilvin, United States Indian agent at Prairie du Chien, went on foot from Rock Island to the mouth of the Wisconsin, and reported that the Indians of the region had "mostly abandoned the chase, except to furnish themselves with meat, and turned their attention to the manufacture of lead."[1]

Previous to the Louisiana purchase nearly all the valuable lead mining lands were within the domains of France and Spain. Soon after these lands had passed under the jurisdiction of the United States, Congress, by the act of March 3, 1807, reserved all Government lands bearing lead ores, and authorized leases of these lands. The first leases provided for a 10 per cent royalty on the lead produced; the rate was afterwards reduced to 6 per cent. No leases were issued until 1822, when crowds of prospectors began to enter this region. A few years later the mines gave employment to over 2,000 men, many of them farmers, who with their slaves spent only their spare time in the mines. The royalties were paid with some regularity for a short time only; after 1834, as a consequence of the immense number of illegal entries of mineral land at the Wisconsin land office, the smelters and miners refused to make any further payments, and the Government was unable to collect any royalty from them. After much trouble and expense, it was, in 1847, finally concluded to sell the mineral lands.[2]

The chief lead mining districts, which to-day furnish the bulk of the lead production of the United States, were not developed until much later. The lead deposits of the Joplin-Galena district, embracing southwestern Missouri and part of Kansas, were discovered in 1848, but attracted little attention before the Civil War. The great western deposits of argentiferous galena were discovered in 1864, but could not be worked profitably until the extension of the railroads through that region.

Methods of mining and smelting.—The early methods of lead mining on this continent were extremely crude. The Indians, who during the time of the French dominion were the chief producers, only skimmed the surface, although occasionally they would drift for some distance into the sidehills, and when they reached rock would build a fire under it and crack it by dashing cold water on the heated surface. Their tools, in the earliest times, were buckhorns, many of which were found in abandoned drifts by the first white settlers, but in the eighteenth century they obtained iron implements from the traders to whom they sold their lead. The Indians loaded their ore in the shafts into tough deerskins, the bundle being hoisted to the surface or dragged up inclined planes by long thongs of hide. Many of these leads, abandoned by the Indians when the work of developing them became too great for their simple tools, were found at a later epoch to be among the most profitable in the region.

Improvement in the method of working the mines was very slow for a long time after the advent of white miners. The first shaft in a lead mine in Missouri was sunk about the beginning of the nineteenth century. Schoolcraft, who visited the lead mining district in 1819, found about 40 mines, 4 or 5 of which had regular shafts. There was not an engine of any kind—horse, steam, or water power—for removing water from the mines, several of which, with the richest prospects in view, had been abandoned on this account.

The reduction of lead ore to the metallic state was in the earliest times not differentiated from mining. Any man who found a vein could mine and smelt the ore roughly himself. The methods of smelting were crude in the extreme. A hole was dug in the ground and lined with rocks. This was usually located on a hillside for the purpose of getting a strong air draft. Hollow log heaps were reared; the centers were filled with mineral; then as much wood as possible was piled on top of and around the heaps, and the mass was fired, with the result that a portion of the ore was smelted and ran into trenches in the ground. Sometimes this operation had to be repeated three times. Rough pigs run into a scooped-out hollow in the earth itself, and weighing about 75 pounds, were usually made by the Indian squaws. This method of smelting was wasteful, but since the supply of ore was apparently unlimited the same practice was followed as late as the first quarter of the nineteenth century by white miners, as well as by operators who worked their mines with slave labor. About that time smelting began to be specialized by ore buyers as a separate occupation. The methods of reduction practiced in those days are thus described by Schoolcraft:

> Having raised a sufficient quantity of ore for smelting, the next process consists in cleaning the ore from all extraneous matter. This is done by small picks, tapered down to such a point that a careful hand may detach the smallest particle of adhering spar. It is necessary that the ore should be well cleaned, for it would otherwise prove refractory in smelting. If there be any lumps of uncommon size, these are beaten smaller. The object is to bring the lumps as near as may be to a uniform size, so that the heat may operate equally in desulphurating the ore. It is desirable that the lumps should be about the bigness of a man's two fists, or about 15 pounds in weight; if too small, a difficulty and a waste is experi-

[1] Early Lead Mining in Illinois and Wisconsin, by Reuben Gold Thwaites, in Report of American Historical Association, 1893, page 191ff.

[2] Metallic Wealth of the United States, by J. D. Whitney, page 405.

enced in smelting. In this state the ore is conveyed to the furnace and piled on the logs prepared for its reception. When the charge is put in, which may in a common way be about 5,000 pounds, it is surrounded by logs of wood and covered over at the top and the fire is lit up at the mouth below. A gentle warmth is given at first, which is raised very gradually and kept at this point for about twelve hours to allow the sulphur to dissipate; the heat is then increased for the purpose of smelting the ore, and in twelve hours more the operation is completed and the lead obtained. Wood is occasionally added as the process goes on, and there is a practical nicety required in keeping the furnace in proper order, regulating the draft of air, etc., so that some smelters are much more expert, and thereby extract a greater quantity of lead from a like body of ore than others. This furnace is called the log furnace, and so far as I know, is peculiar to this country. It is of very simple construction, consisting of an inclined hearth, surrounded by walls on three sides, open at top, and with an arch for the admission of air below, and upon the whole it appears well adapted to the present situation and circumstances of the people. It is cheap, simple, may be built at almost any place, and answers the purpose very well. A good furnace of this kind may be built at an expense of from $50 to $60, every expense considered.[1]

It does not seem from this description that the white miners and smelters had by that time made much improvement upon the primitive methods of the Indians. It was not before 1836 that the log furnace was superseded by the blast furnace.

Ignorance of scientific methods caused the early miners to throw away the lead carbonate, or cerussite, which they called "dry bone" and considered worthless. It accumulated in great heaps until the arrival, in 1838, of a German named Hagen, who knew the value of "dry bone," and erected furnaces for its reduction. The result of the utilization of the cerussite was a largely increased production.

Utilization of zinc ore.—The ignorance of the practical miner likewise retarded the utilization of zinc ores, which are associated with lead ores and now constitute the chief value of the output of the zinc-lead mines. The presence of zinc in the lead mines of the Mississippi valley was noted by Schoolcraft, who wrote as early as 1819:

> Considering the rarity of this metal in America, and its extensive usefulness, which is yearly increasing, I have no doubt it will shortly attract the attention of some capitalist and become a source of much profit.[2]

It took, however, more than half a century before the prediction was fulfilled. Whitney, writing thirty-five years later, gave expression to the following view:

> No one acquainted with the manufacture of zinc ores into metal or oxide would recommend the establishment of works for this purpose in the western lead region, as the business can not be made profitable against the competition of the Belgian and Prus sian manufactories, except under the most favorable circumstances of situation and an abundant supply of ore which can be obtained without any considerable mining cost. The zinc deposits of the West do not satisfy these conditions either as regards quantity or quality of the ore or of the proximity of fuel.[3]

These words of one who was an expert in his own time have a peculiar sound to-day, when it is considered that over $8,000,000 was won from the western zinc deposits in 1902.

For over half a century zinc ore was taken out of the mines of the southwestern part of Missouri, in connection with lead ore, and thrown upon the dump pile as worthless. Mines were deserted because of the prevalence of this refuse or "tiff," as it was called by the miners. In the early seventies this peculiar looking substance, which was causing the lead miners so much trouble, was examined by a geologist and pronounced to be zinc ore. A carload of it was shipped to Lasalle, Ill., for treatment. The smelter returned $15 for the carload, telling the shippers that it was a high grade of zinc ore. This led to further shipments of the ore. Abandoned mines were gradually reopened because of the zinc ore they contained, and in 1902 the zinc product of Missouri was more than eleven times the value of all the zinc ore mined in the Eastern states, where zinc mining dates back to 1848, and where the mines were the main source of the domestic zinc supply previous to the development of the Joplin-Galena district.

Business organization.—The last twenty years in the history of the lead-zinc mining industry have been a period of change. A contemporaneous description of the business methods of twenty years ago is given in the following excerpts:

> When a good prospect is discovered in new ground the land around it is leased from the original owners on royalties ranging from 10 to 25 per cent by a number of individuals, who organize various mining, or, as they would more properly be called, land companies. These companies have the land divided up into lots 200 feet square, and a plat of it made; select certain lots for themselves, and throw the others open to miners. They usually start a shaft on one of their own lots, and put in a pump. If the indications continue good, many of the lots, particularly those near the pump shaft, are quickly taken up by parties of miners who sink shafts upon them, timber the ground, put up hoisting contrivances, furnish all supplies, and bear all expenses.
>
> When ore is struck it is drifted on and followed in all directions up to the boundaries of the lot in question. The ore is raised to the surface and crushed and washed by the miners, and is sold to one of the zinc or mineral buyers. It is weighed over the company's scales, and paid for to the company, which deducts a royalty of 25 per cent on zinc blends and 50 per cent on "mineral" (galena); and if it has pumps running, a pump rent of $1 a ton on zinc ore and $2 on 1,000 pounds of galena; and pays over the balance to the miners. The royalties, of course, vary with circumstances, but the above are general.[4]

With a few exceptions all the mining was done by small companies, mostly unchartered associations of persons living in the immediate neighborhood. Some storekeeper, farmer, or local capitalist furnished the small amount of money needed for tools; and the men who worked in the ground in winter usually engaged in farm work during the summer. The ore was generally raised to the surface by a windlass, and cleaned by hand

[1] View of the Lead Mines, by Henry Rowe Schoolcraft, pages 93 and 94.
[2] Ibid., page 56.

with a "pickawee" hammer, or crushed with a "bucking iron" on a flat stone, or by an itinerant horsepower crusher, and was concentrated by sluicing and hand jigging. The holders of lots sometimes put up crushing and washing machinery on their lots.

The machinery is usually of the simplest description—a farm or small stationary engine, covered by a shed of rough boards, a small-sized Blake's breaker, set over a pair of rolls, and a horse whim or a whip. The jigs are ordinary hand jigs, with an overhead breakstaff, working a sieve 2 by 3½ feet up and down in a box of water. The jigging is usually done by contract, and is paid for by the ton of cleaned ore. It is common to see from 10 to 20 of these jigs grouped together under a shed of poles, covered with branches of trees or rough boards.[1]

The smelting companies which drew their ore supply from this district had their resident or traveling purchasing agents. Most of the miners were poor and unable to work their diggings to good advantage, or to hold their ore long after it was cleaned.

The labor was to a considerable extent performed by miners working upon their own account. Men with no capital but their picks and shovels would lease small mining lots and try their luck. The advantages of the leasing system to the landowner and mine operator, as compared with the regular wage system, are further explained in the same article. The miners, working on their own account, with hopes of large ultimate gains, have every inducement to work hard and cheaply, and to follow every clew that working prospectors, who, during the season wander from place to place, and follow every real or supposed indication of ore, may find.

How else, it may be asked, could prospecting be so well or so cheaply done? And there is a class of enterprising, skillful, well-to-do miners, naturally associated as partners, who have made one or more good strikes, and are always ready to take hold of any new venture that promises well, either in working a lot or in forming a land company to open new mines. Where else could be found capitalists so willing to risk their money in a speculative venture? Men of this sort are always ready and able to work themselves, or to direct the work above or below ground. How else could be obtained as willing and as watchful superintendents, foremen, and clerks?[2]

The leasing system has maintained itself up to the present day in zinc mining. A comprehensive description of this system is given in a recent pamphlet by a local expert, Mr. Frank Eberle:

The methods of mining and handling zinc ore are * * * unlike those used in mining for other minerals. The first step necessary is to secure the land upon which to begin operations. Zinc mining lands are seldom sold, their owners preferring to lease them on royalty. Virgin lands, or those on which no mineral has been found, or which have never been prospected for mineral, are leased at 10 per cent royalty, that is to say, the landowner leases the land and agrees to take as payment one-tenth of all the ore obtained from his land. The company or individual who secures the lease then divides the tract up into 1-acre mining lots and prospects the land with a steam drill in several places to ascertain whether the land contains mineral, and where the best bodies of ore are located, their depth, thickness, and the force of water that the miners will have to contend with. When the land has been sufficiently prospected, lots are then subleased to miners at 20 per cent royalty, which means that the miners must give 20 per cent, or one-fifth, of the ore to the company or individual holding the original lease. Out of this 20 per cent the original lessee must pay the landowners 10 per cent, and generally he must also undertake to put in pumping plants, to keep the tract drained, where the water is so strong as to interfere with mining. The miners lease one or more lots from the lessee of the tract, and begin operation by sinking a shaft. * * *

The zinc ore, or "jack," is purchased at the mines by "jack" buyers representing American and European smelters. These buyers * * * bid on the week's output of zinc ore. They make an offer of so much a ton for all of the ore to be taken out of the mine during the week. If the offer is accepted, the "jack" buyer sends his wagons to the mines, and hauls the ore to the cars for shipment to the smelters for which he buys. Every Saturday evening is settling-up time. Then the mine owners, miners, and ore buyers assemble in the various towns in the district, and the ore buyer draws a check for the ore purchased from each mine. The check is made payable to the landowner upon whose property the ore was mined. He takes out his 10 per cent royalty, and passes the balance to the original lease holder, who takes out his 10 per cent royalty and gives the balance to the mine operator, who pays his operating expenses out of the share he receives.[3]

The larger companies which have their own smelters buy all the ore from their lessees at a stipulated price, deducting from the same their royalties.

Mining in a small way.—It is of great theoretical and practical interest to note the special conditions which have permitted of the survival of zinc-lead mining on a small scale, and often with primitive methods, amid concentration of ownership in mineral lands.

The subject is treated from a technical point of view in the Twenty-second Annual Report of the United States Geological Survey, from which the following is quoted:

The individual ore bodies are rarely large. The mines must accordingly be short lived, and the plants must be built to meet that condition. In a district where it is cheaper to sink a new shaft than to tram ore 600 or 700 feet underground, central shafts of large capacity are out of place. Large central mills to which the ore of a whole tract is brought are not considered a good investment. In hauling 100 tons of 10 per cent ore 90 tons of waste drift are moved, and when simple and effective mills of small capacity are so easily and cheaply built and run, individual mills are to be preferred, even though the larger mill be able to make a slight saving per ton in mill charges. It is difficult to supply dirt steadily enough to keep a large mill running, and loss of time is more costly with a large than a small plant. The mills of the district * * * are very simple, and are developed on the principle of using a rougher jig before cleaning, instead of attempting close sizing. The result is a very great capacity at small cost. The saving is not so close as in a well-run sizing mill, but the extra ore saved by the latter is not in this district worth the added cost.

of saving it. * * * A hundred-ton mill can be built in the district at a general price of $6,500 to $7,000, and the opening and equipping of a mine costs ordinarily, approximately, $10,000. The mill can be run by four men. To that number must be added a hoisterman and an underground force. * * * The mill and plant are of such style as to be readily torn down and moved when the particular ore body is worked out, and the whole plant is designed for rapid work. Economy is sought in first cost rather than in refinements of efficiency. * * * The whole style of equipment and the methods of mining and milling are designed to meet the conditions of short-lived individual deposits of low-grade ore.[1]

The higher cost of running small plants, as compared with mines operated on a large scale, comes from the expensive methods of generating and distributing power, but it is the opinion of Mr. Bain that, with modern methods of power transmission, this difficulty can be overcome by the development of central power plants.

[1] Twenty-second Annual Report of the United States Geological Survey, Part II, 1900–1901. Preliminary report on the lead and zinc deposits of the Ozark region, by H. F. Bain, page 227.

Though the actual operation of the mines is to some extent still conducted on a small scale, the tendency toward combination has not been without effect upon the zinc-lead mining industry.

Both the productive capacity and the consumptive demand for spelter have been centralized in a striking manner. Upward of 50 per cent of the consumption of spelter in the United States is for the purpose of galvanizing iron, which business is now chiefly in the hands of the constituent companies of the United States Steel Corporation. The manufacture of sheet zinc is in the hands of four companies. The manufacture of brass in Connecticut, which is the principal center of that industry, is controlled by one company. The consumption of spelter for use in the desilverization of lead is also chiefly in the hands of one corporation. It is safe to say, therefore, that 75 or 80 per cent of the demand for American spelter now comes from seven corporations. On the other hand, the production of spelter has also been centralized, practically the whole of the active smelting capacity being now divided among seven concerns.[2]

COPPER ORE

COPPER ORE.

By Isaac A. Hourwich, Ph. D.

The statistics for copper ore in this report are those of mines producing ores, the principal or only value of which is their copper contents. The statistics for ore dressing works (stamp mills and concentrating plants) connected with copper mines are included in the returns. Copper is recovered also as a by-product of the smelting of ores valued chiefly for their precious metal contents. All statistics relating to the mining of these ores are included in the returns for gold and silver mines. Smelters are regarded as manufacturing establishments and were included in the Report on Manufactures of the Census of 1900.

The following table is a comparative summary of the statistics of copper mines from 1860 to 1902:

Table 1.—COMPARATIVE SUMMARY: 1860 TO 1902.

	1902	1889[1]	1880	1870	1860
Number of mines	144	(2)	42	[3]40	[3]47
Number of operators	144	(2)	(2)	(2)	(2)
Salaried officials, clerks, etc.:

Salaries	$1,768,456	$123,236	(6)	(5)	(5)
Wage-earners:					
Average number	26,007	[4]9,750	6,039	5,404	5,153
Wages	$21,151,405	$6,610,781	[6]$3,214,031	$2,706,264	$1,816,160
Contract work	$188,768	$337,061	(2)	(2)	(2)
Miscellaneous expenses	$1,397,465	$1,852,758	(2)	(2)	(2)
Cost of supplies and materials	$11,083,175	$5,638,694	$1,391,826	$586,844	$506,814
Product:					
Quantity of ore mined, short tons	11,780,064	3,322,742	1,007,490	(2)	(2)
Copper contents of ore shipped and milled, pounds	625,004,529	220,569,438	56,115,454	(2)	(2)
Value at mine of ore shipped and milled	$51,178,036	(2)	[7]$8,856,869	$5,201,312	$3,361,222

[1] Detailed figures shown only for Michigan, Montana, Arizona, and New Mexico.
[2] Not reported.
[3] Establishments.
[4] Foremen included in wage-earners.
[5] Not reported separately.
[6] Salaries included in wages.
[7] Value of 5,410,546 pounds of copper for Western states and 153,880 pounds for Tennessee not reported.

During the forty-two years covered by the table the growth of copper mining has been very marked, the value of products having increased $47,816,814, or over fourteenfold. The increase in the total wages was $19,335,245, or nearly elevenfold.

It was found that in most of the active mines no separate account was kept for development work. The expenses of producing mines, therefore, include the cost of development work incidental to mining. Considerable development work was done in mines that reported no production. Most of them were located in the Western states, where the mineralogical character of the ore was described as auriferous and argentiferous copper, yet it would not be practicable to classify such mines as copper, or gold and silver mines, in accordance with the chief valuable element of the ore, before they have become regular producers. In most cases the work was prosecuted in the expectation of developing a gold and silver mine. All such mines were, therefore, classed as gold and silver mines. Distinctively copper mines in the development stage were reported from the following states: Michigan, 10 mines; Wisconsin, Maryland, Georgia, Tennessee, and Missouri, 1 mine each. The statistics for these mines are not included in the preceding summary for producing mines, but are presented separately in the following statement:

Development work: 1902.

Number of mines	15
Number of operators	15
Salaried officials, clerks, etc.:	
Number	55
Salaries	$64,208
Wage-earners:	
Average number	302
Wages	$184,424
Contract work	$200
Miscellaneous expenses	$38,530
Cost of supplies and materials	$135,847

Number of mines and operators.—The terms "mine" and "operator," as used in this report, require a word of explanation. In some cases certain properties were combined by the owner under one management and reported as one mine, while others were operated as separate mines and so reported. When a "group" of mines was included in one report, it was very largely a matter of opinion whether all or some of the properties constituting the group were to be considered as separate mines, or whether all properties had been merged into one mine. The only reliable unit of enumeration was the reporting corporation, firm, or individual. Among these were 2 corporations whose mines were operated by lessees and 1 holding company, the Amalgamated Copper Company. The capitalization of the first two was a distinct element of the capital invested in copper mining, quite independent of the capital invested by the lessee, and it was believed, therefore, that this ought to be included in the total capitalization reported for the copper mining industry. As regards the Amalgamated Copper Company, it is a matter of opinion whether it or the companies whose entire stock is owned by it should be regarded as the actual operators. It was therefore thought preferable to show in the tables the total number of companies reporting. If the holding company and the two lessors are excluded from the total number reporting, then the number of operators was 141. If, on the other hand, the constituent companies of the Amalgamated Copper Company are excluded, then the total number of operators was 136.

Character of ownership.—The corporate form of ownership was the predominating type in the copper mining industry. Of the 144 operators 100 were incorporated companies, 23 were firms or limited partnerships, 19 were individuals, 1 was a cooperative association, and 1 was an estate. In Michigan all copper mining operators were incorporated.

A summary of all copper mines, classified by character of ownership, is presented in Table 2.

TABLE 2.—*Summary, by character of ownership: 1902.*

	Total.	Individual.	Firms, etc.[1]	Incorporated companies.
Number of operators	144	19	25	100
Salaries	$1,768,456	$27,095	$23,395	$1,717,966
Wages	$21,151,405	$434,059	$138,048	$20,579,298
Contract work	$188,768	$1,100	$4,100	$183,568
Miscellaneous expenses	$1,397,465	$31,084	$7,620	$1,358,761
Cost of supplies and materials	$11,083,175	$202,516	$70,693	$10,809,966
Ore shipped and milled:

Ore smelted	$63,474,278	$352,237	$12,928	$63,109,113

[1] Includes 2 mines classed under "other forms."

It appears from the preceding table that the share contributed by each class of operators to the output of the mines was as follows: Incorporated companies, $50,421,837, or 98.5 per cent; individuals, $594,377, or 1.2 per cent; firms, $161,822, or three-tenths of 1 per cent. About three-fourths of the copper ore mined by individuals and firms was sold in the crude state, the remaining one-fourth being dressed or smelted at the mine. The incorporated companies, on the contrary, sold only 6 per cent of their ore in the crude state, namely, a product valued at $4,595,588; the value of dressed ore sold by them was $8,611,415, or 11.3 per cent, and that of ore smelted at the mine or shipped to smelters operated by the same companies was $63,109,113, or 82.7 per cent.

Capital stock of incorporated companies.—The capitalization of the incorporated companies is shown in Table 3. In the consideration of the capitalization of the copper mining companies, it should be borne in mind that a portion of the capital stock of some of them represented the value of smelting plants owned and operated by the same companies.

TABLE 3.—CAPITALIZATION OF INCORPORATED COMPANIES: 1902.

As shown in Table 3, the division of stock into common and preferred is not general with copper mining companies. There were only 6 companies reporting both common and preferred stock; up to the close of the year 1902, 1 of these had issued no stock of either kind. The issue of bonds was not favored generally by copper mining companies; there were only 6 companies having bonded indebtedness, and of the $6,950,000 of bonds authorized, $6,075,530 were issued. Assessments on stock were also unusual, the total amount levied by all companies since organization being only $7,725,748.

The following table shows each class of capital stock, authorized and issued, in detail:

TABLE 4.—INCORPORATED COMPANIES, GROUPED BY CLASS OF STOCK: 1902.

CLASS OF STOCK REPORTED.	Number of incorporated companies.	AUTHORIZED.			ISSUED.		
		Total.	Common.	Preferred.	Total.	Common.	Preferred.
Total	100	$441,788,125	$429,321,625	$12,466,500	$372,240,270	$361,388,770	$10,851,500
Both common and preferred	[1] 6	92,833,125	80,366,625	12,466,500	56,816,597	45,965,097	10,851,500
Common only	94	348,955,000	348,955,000	.....	315,423,673	315,423,673	.....

[1] One company had issued no common or preferred stock up to the close of 1902.

The capital stock shown in Table 3 includes a duplication since the capitalization of the Amalgamated Copper Company, as well as that of its constituent companies, is reported. Table 5 shows the capitalization of the Amalgamated Copper Company and each of its constituent copper mining companies. Neither the parent company nor any of its constituent companies has preferred stock. The Amalgamated Copper Company owns the entire capital stock of the Colorado Smelting and Mining Company, and of the Washoe Copper Company, and a controlling interest in the others.

TABLE 5.—CAPITALIZATION OF THE AMALGAMATED COPPER COMPANY AND ITS CONSTITUENT COMPANIES: 1902.

COMPANY.	COMMON STOCK.				BONDS.			
	Authorized.		Issued.		Authorized.		Issued.	
	Shares.	Par value.	Shares.	Par value.	Number.	Par value.	Number.	Par value.
Amalgamated Copper Company	1,550,000	$155,000,000	1,538,880	$153,888,000	.....	.....	.....	.....
Anaconda Copper Mining Company	1,200,000	30,000,000	1,200,000	30,000,000	.....	.....	.....	.....

Washoe Copper Company	200,000	20,000,000	30,464	3,046,400	.....	.....	.....	.....

Dividends.—The total amount of dividends paid in 1902 was $14,116,002. Of this amount, $3,077,760 was paid by the Amalgamated Copper Company. These dividends were derived partly from the dividends declared by its constituent companies, and partly from the earnings of other properties of the Amalgamated Copper Company, such as coal mines, railways, etc. The following table shows the capitalization and dividends of all dividend paying companies, with the exception of the Amalgamated Copper Company, and also the capitalization of the companies that paid no dividends in 1902:

TABLE 6.—INCORPORATED COMPANIES, CLASSIFIED WITH RELATION TO DIVIDENDS, CAPITAL STOCK, AND BONDS: 1902.[1]

	CAPITAL STOCK AND BONDS.						
	Authorized.			Issued.			
	Number of shares or bonds.	Par value.		Number of shares or bonds.	Par value.		Dividends or interest paid.

Preferred stock	1,500,000	1,500,000	1.00	300,000	300,000	1.00	.....
Bonds	2,650	2,650,000	1,000.00	2,575	2,575,000	1,000.00	132,500

[1] Exclusive of the Amalgamated Copper Company.

There were 18 dividend paying companies, with capital stock issued to the value of $113,462,927; whereas 81 companies, with capital stock issued to the value of $104,889,343, declared no dividends. Dividends on $10,551,500 of preferred stock were declared by 4 companies; the rate of dividends averaged 4.3 per cent. No dividends were declared by these companies on their common stock, which was issued to the amount of $45,965,097. Two companies with preferred stock authorized declared no dividends; the authorized preferred stock of these companies was $1,500,000; the amount issued, $300,000.

Dividends on common stock were declared by 14 companies with an authorized capitalization of $75,150,000, of which $56,946,330 was outstanding; no preferred stock was authorized by these companies. The average rate of dividends on common stock was 18.6 per cent.

A comparison between the par values of dividend paying and nondividend paying stocks is not without interest. The average par value per share of dividend paying common stock was $21.07, whereas the average par value of a share of common stock on which no dividends were declared was only $4.11. Similarly, the par value per share of preferred stock was $10.71 for dividend paying and only $1 for nondividend paying companies. It is apparent that the type of mining enterprises, for which capital stock is issued at $1 and less per share, is more frequent among nondividend paying than among dividend paying companies. The latter are, for the most part, concerns the capital stock of which is issued at prevailing commercial values per share, viz, at $25 and over.

The following statement shows the stock and bonds on which dividends and interest were paid:

Classes of stock and bonds on which dividends and interest were paid: 1902.

CLASS.	Number of companies.	Authorized.	Issued.	Dividends or interest paid.	Per cent.
Common stock	14	$75,150,000	$56,946,330	$10,589,252	18.6
Preferred stock	4	10,966,500	10,551,500	448,990	4.3
Bonds	4	3,800,000	3,001,000	174,500	5.8

The total amount of interest paid on bonds was $174,500, of which $132,500 was paid by companies that declared no dividends in 1902. The rate of interest on bonds averaged 5.8 per cent.

A number of corporations operated both copper mines and smelters, and some were interested in other properties, such as coal or iron mines, railways, etc. The dividends reported for such companies were derived from all those sources and can not be segregated.

A comparative summary of dividend paying companies—with the exception of the Amalgamated Copper Company, which, being merely a holding company, is therefore excluded—and those which declared no dividends in 1902, is presented in Table 7.

TABLE 7.—*Comparative summary of dividend paying and nondividend paying companies: 1902.*[1]

	Total.	Dividend paying companies.	Nondividend paying companies.
Number of companies	99	18	81
Salaries	$1,712,306	$724,774	$987,532
Wages	$20,579,298	$10,357,693	$10,221,605
Contract work	$183,568	$92,384	$91,184
Miscellaneous expenses	$1,358,761	$512,955	$845,806
Cost of supplies and materials	$10,809,966	$6,163,479	$4,646,487
Ore shipped and milled:			
Short tons	11,296,857	5,762,972	5,533,885
Value of product at mine, total	$50,421,837	$32,605,752	$17,816,085
Average per company	$509,311	$1,826,589	$216,583

Silver	$5,466,924	$2,849,871	$2,617,053
Gold	$1,782,273	$1,166,286	$615,987
Other metals	$17,986	$15,527	$2,459
Total gross value	$76,316,116	$47,267,337	$29,048,779
Average per ton	$6.75	$8.20	$5.25
Crude ore sold	$4,595,588	$2,617,567	$1,978,021
Dressed ore sold	$8,611,415	$903,074	$7,708,341
Ore smelted	$63,109,113	$43,746,696	$19,362,417

[1] Exclusive of the Amalgamated Copper Company, which is merely a holding company.

It must be borne in mind that the payment of dividends in a given year is not indicative of profits earned during that year. Dividends may be declared from the accumulated surplus of former years. On the other hand, the failure to declare a dividend does not necessarily show a loss; the earnings may have been invested in development work, in new equipment for the plants, in acquiring new property, etc. Some of the principal copper mining companies are close corporations, the stock of which is held by a limited number of persons. As the shares are not on the market, it is often a matter of indifference to the stockholders whether a dividend is declared or the net earnings are accumulated as a surplus.

The chief differences disclosed by the preceding table between the dividend paying corporations and those which paid no dividends in 1902 are as follows:

First. The grade of ore mined was higher with the former than with the latter, viz, $8.20 per ton as against $5.25 per ton.

Second. Where dividends were paid the ore was nearly all smelted at works connected with the mines, whereas in other cases much of the ore was sold.

Third. The average value of product per dividend paying company was $1,826,589, while the average for other companies was only $216,583; apparently it was the largest companies that declared dividends in 1902.

The census returns for 1902 cover a year of low prices of copper. A comparison with the dividends for previous years will be found on a subsequent page, in connection with a study of prices.

Employees and wages.—Wage-earners constituted 95.6 per cent of the total number of employees, and their wages were 92.3 per cent of the total salaries and wages. Table 8 shows, by states and territories, the average number of men, and of boys under 16 years of age, employed during each month.

TABLE 8.—AVERAGE NUMBER OF WAGE-EARNERS EMPLOYED DURING EACH MONTH: 1902.

	United States.	Arizona.	California.	Colorado.	Michigan.	Montana.	New Mexico.	Utah.	All other states and territories.

November	91	50	.....	.....	27	.....	.....	.....	14
December	93	50	.....	.....	29	.....	.....	.....	14

The average number of wage-earners was greatest, 27,183, in May, and least, 24,768, in February; the variation during the year was not marked.

In the following table the average number of wage-earners at certain specified rates of pay is shown for the various classes of employees, and also the percentage which the number at each rate forms of the total number in the class:

TABLE 9.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

RATE PER DAY (DOLLARS).	All occupations.		Engineers.		Firemen.		Machinists, blacksmiths, carpenters, and other mechanics.		Miners.		Miners' helpers.		Timbermen and track layers.		Boys under 16 years.		All other wage-earners.

[1] Includes 2,206 miners, all in Michigan, who were paid in accordance with the amount of work done; for these the figures shown in this table represent average daily earnings.
[2] Less than one-tenth of 1 per cent.

The range of wages for the bulk of the employees was from $1.50 to $3.74, 24,324 wage-earners, or 93.5 per cent of the total number, being included between those rates. Practically all those classed as miners were paid at least $2 per day, and 5,552 of them, or 43.3 per cent, received between $3.50 and $3.74. Most of the highly paid miners were reported from Montana and Arizona. Of those classed as miners' helpers, 1,257 in all, 66.3 per cent were paid between $1.75 and $2.24, 22.1 per cent having received less than $1.75, and 11.6 per cent, $2.25 or over. There was a wide range in the rates paid to timbermen and track layers; 454, or 52.6 per cent of the total number, were paid between $1.75 and $2.24, and 24 per cent, from $3.50 to $3.74. Practically all of the timbermen and track layers at $3.50 or over were reported from Montana.

There was also a wide range in the rates for engineers, firemen, machinists, and other mechanics. In each of these three classes more than 90 per cent of the wage-earners received $1.75 per day or over. The proportion receiving $3.50 or over was as follows: Engineers, 43.6 per cent; firemen, 28.3 per cent; and machinists and other mechanics, 42.6 per cent. In each case the greatest number at rates of $3.50 or over were reported from Montana and Arizona.

The number of boys under 16 years employed was small, only 103, or less than five-tenths of 1 per cent, having been reported. Their rates varied from 50 cents to $2.49 a day. Of the 103 boys, 50 were employed in Arizona and 37 in Michigan.

The 8,105 employees grouped under "all other wage-earners" constituted 31.2 per cent of the total number. Their duties were so varied as to render impossible any separation into well-defined occupations. The rates of pay for the greater portion of these wage-earners ranged from $1.50 to $2.24 per day, 74.3 per cent being included between those rates.

The following table shows the distribution of wage-earners according to daily rates of pay, by states:

TABLE 10.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY STATES: 1902.

[Each cumulative percentage shows the proportion of the total number receiving a wage as great as, or greater than, the lowest wage of the given wage group.]

[1] Includes 2,206 miners paid in accordance with the amount of work done; for these only average daily earnings were obtained.
[2] Less than one-tenth of 1 per cent.

Only Arizona, Michigan, and Montana are shown separately. These 3 states gave employment to 24,072 wage-earners, or 92.6 per cent of the total number employed in mines, the principal product of which was copper ore. Of the 3 states, Montana shows by far the highest rates, 6,095 wage-earners, or 95.4 per cent of the total number, receiving $3.50 per day or over. In Arizona 37.5 per cent of the wage-earners received $3.50 or over per day, and 40.1 per cent from $1.75 to $2.49. In Michigan the wages paid were much lower than in either Arizona or Montana, practically all of the men employed in copper mines in that state receiving between $1.50 and $2.74.

The 1,935 wage-earners grouped under "all other states" are distributed among 13 states, no single state reporting as many as 500.

The tenacity of antiquated forms of industrial relations is exemplified in the few copper mines where labor was performed on a share of the product. This form of employment is frequently found in gold mines, where the miners so employed are locally known as "leasers," "tributers," etc. There were only 7 cases of this kind reported at copper mines, namely, 4 in Montana, of which 3 were in Silverbow county; 2 in Arizona; and 1 in Colorado. In all, 22 men besides the regular wage-earners found employment on such terms in these mines. The total output was valued at $25,567 at the mines, the output of no mine exceeding $10,000 in value. The percentage of copper in the ore varied from 6 to 29 per cent. The share received by the mine owner ranged from 10 to 20 per cent of the gross value of the ore, and from 10 to 25 per cent of the value at the mine, after smelting and freight charges were deducted. The miner, out of his share of the product, furnished his own supplies.

Days in operation.—In the following table 126 copper mines are classified by the number of days in operation; 18 of the 144 mines failed to report on this subject:

TABLE 11.—*Number of mines, classified according to time in operation, by states and territories: 1902.*

Miscellaneous expenses.—This item includes rent and royalties of all descriptions, "taxes, insurance, interest, advertising, office supplies, law expenses, injuries and

damages, telegraph and telephone service, gas, and all other sundries not reported elsewhere." The total amount reported under this head was $1,397,465. Of this amount $130,215 was paid in rent and royalties, viz, $33,184 in royalties for mine and mineral land, $22,393 in water rents, and $74,638 in other rents and royalties. On the whole, royalties and rents were but an insignificant item in the copper mining industry. All other miscellaneous expenses aggregated $1,267,250.

Supplies and materials.—The general term "materials" has scarcely any application to copper mining. The "material" operated upon in a mine is the rock underground. The inquiry calling for "total cost of supplies and materials of all kinds used during the year" at the mine contained the following explanatory note:

"The cost of the following materials should be reported under this inquiry: Lumber and timber used for repairs, mine supports, track ties, cars, and all other purposes; iron and steel for blacksmithing, rails, frogs, sleepers, etc., for tracks and repairs, parts of machinery and tools used for renewals and repairs; explosives, water for boilers and for other purposes, fuel, illuminating and lubricating oils, machinery supplies, etc."

All the items here enumerated strictly come under the definition of "supplies." The "material" treated at the mills is the ore which comes from the mine. It is not customary in mining bookkeeping to charge the mill with the value of the ore brought from the mine. In the schedule relating to "reduction works, other than smelters," there were two separate inquiries, one relating to "materials," the other to "supplies." The former called for a statement of the "character of materials used, whether ore, tailings, or other materials," and was confined to "materials bought in 1902." The amount reported in answer to this inquiry is not included in the "cost of supplies and materials" shown in Table 1, but is given as a separate item. Purchased ores formed but a very insignificant part of the total tonnage treated at mills connected with copper mines, namely, 1,068 tons out of a total of 6,558,222 tons treated in 1902.

The explanatory note to the inquiry relating to mill "supplies" enumerated: "Shoes, dies, screens, plates, and other parts of machinery and tools used for renewals and repairs; quicksilver, cyanide of potassium, lumber, iron, steel, oil, fuel, water, etc." The total cost of "supplies and materials," as herein defined, was reported as $11,083,175.

Mechanical power.—The total primary power of all classes used in copper mines aggregated 198,507 horsepower, of which more than two-thirds, viz, 137,772 horsepower, was used in Michigan, and one-fourth, viz, 49,090 horsepower, in Montana. The quantity of power used had no relation to either the value of the product or the copper contents of the ore, but was roughly proportionate to the quantity of crude ore mined, as appears from the following statement:

Horsepower used and tons mined, by states and territories: 1902.

STATE OR TERRITORY.	Total horsepower.	Tons mined.	Horsepower, per cent.	Tons mined, per cent.
United States	198,507	11,780,064	100.0	100.0
Michigan	137,772	6,247,317	69.4	53.0
Montana	49,090	3,428,860	24.7	29.1
All other states and territories	11,645	2,103,887	5.9	17.9

The predominating form of power used in 1902 was steam. The total horsepower used, including all primary power owned and electric power rented, was divided as follows: Steam, 189,426, or 95.4 per cent; compressed air (described in the tables as "other power"), 5,235, or 2.6 per cent; gas or gasoline, 1,184, or six-tenths of 1 per cent; water, 326, or two-tenths of 1 per cent; and rented power, all electric, 2,336, or 1.2 per cent. In addition there were 50 electric motors, having a capacity of 2,312 horsepower.

The average horsepower per mine was 1,379. The power supplied by all mines to other establishments was only 87 horsepower. Twelve mines in Silverbow county, Mont., 1 mine in Salt Lake county, Utah, and 1 in Shasta county, Cal., were supplied with power by other establishments. The arrangement was apparently made feasible by the proximity of mining centers like Butte or Salt Lake City. The mine in Shasta county was supplied by a San Francisco power company from one of its substations located in the mountains.

The total number of steam engines was 792, or an average of 5.5 per mine, with an average capacity of 239 horsepower per engine. The total number of gas or gasoline engines was 35, with an average capacity of 34 horsepower per engine. They were reported from 13 mines, of which 1 used also steampower and 1 waterpower. The total number of electric motors was 50, with an average capacity of 46 horsepower per motor. Electric power was reported from 18 mines, nearly all very large producers, namely, 5 with an output exceeding $1,000,000; 8 with an output ranging from $500,000 to $1,000,000; 1 with a product above $250,000, but less than $500,000; 1 with a product above $100,000, but less than $250,000; 1 with a product above $50,000, but less than $100,000; and 2 with a product less than $10,000, of which 1, however, expended during the year more than $250,000 in development work. Compressed air was reported from 16 mines, of which 8 were located in Montana. Waterpower was reported from 6 mines, of which 2 used also steampower and 1 a gas engine. There were in all 8 water wheels in use, with an average capacity of 41 horsepower per wheel.

The exclusive use of gas or water power is characteristic of mining on a small scale. Of the 41 mines coming under the description of small mines there was none with an output exceeding $50,000, while for 7 the value of the product was between $10,000 and $50,000, and for 15 it was between $1,000 and $10,000. At 2 mines

a little over $10,000 each was expended, in 1902, in development work with but small returns.

The use of steampower in copper mines in 1870, 1880, and 1902 is shown in the following statement. No information for 1889 is available.

Steampower used: 1902, 1880, and 1870.

YEAR.	Total number of mines.	NUMBER OF ENGINES.		HORSEPOWER.		
		Total.	Average per mine.	Total.	Average per engine.	Average per mine.
1902	144	792	5.5	189,426	239	1,315
1880	41	135	3.3	13,511	100	330
1870	[1]40	93	2.3	6,328	68	158

[1] Establishments.

Within the past twenty-two years the average number of steam engines, the total horsepower used, and the average horsepower per engine have grown in a remarkable degree. On the other hand, the use of waterpower had practically been discarded in copper mines as early as 1870. The total number of water wheels reported at the Ninth Census was 3 with a total of 70 horsepower, as compared with 93 steam engines with 6,328 horsepower.

The following table shows the number of hoists, pumps, and power drills, with the kind of power used to run the same, for Western and Southern states and territories in 1902. No reports on this subject were received from Michigan (which state has reported more than two-thirds of the horsepower used at mines), Nevada, Virginia, and Wisconsin.

TABLE 12.—HOISTS, PUMPS, AND POWER DRILLS, IN WESTERN AND SOUTHERN STATES AND TERRITORIES, CLASSIFIED BY KIND OF POWER USED: 1902.

STATE OR TERRITORY.	Number of mines reporting.	HOISTS, KIND OF POWER.					PUMPS, KIND OF POWER.						POWER DRILLS, KIND OF POWER.			
		Total number.	Steam.	Gas or gasoline.	Compressed air.	Electric.	Total number.	Steam.	Gas or gasoline.	Compressed air.	Water.	Electric.	Total number.	Steam.	Compressed air.	Electric.

Utah	13	12	9	2	1		6	4	1	1			49	3	46	
Washington	1												3		3	
Wyoming	1	1	1													

At the mines reporting there were 228 hoists in use in 1902, an average of about two per mine. Of this number 158 were run by steam, 51 by compressed air, 16 by gas or gasoline, and 3 by electricity. The use of compressed air as a motive power for hoists was practically confined to Montana, there being only 2 engines of that class in operation in Colorado, 1 in California, and 1 in Utah. Of the 3 electric hoists, 1 was used in Arizona and 2 in California.

There were 160 pumps in operation, an average of 1 per mine; practically all were operated by steam, the exceptions being 2 each operated by gas or gasoline, compressed air, and water, and 1 by electricity.

Of the 122 mines reporting machinery, the number reporting power drills was 34. At these mines there were 900 power drills in operation, of which nearly four-fifths were reported from Montana. The motive power was mostly compressed air; only 135, less than one-sixth of the number reported, were operated by steam and only 2 by electricity. Those operated by steam were distributed as follows: Montana, 72; Tennessee, 56; and all other states, 7. In the Tennessee copper mines steam still held the first place, only 17 drills having been run by compressed air.

The following is a statement of the tonnage mined and the wages paid to miners and miners' helpers below ground in mines equipped with power drills and in those not reporting them:

Tonnage mined and wages paid to miners and miners' helpers in mines with and without power drills: 1902.

	Number of mines.	TONS MINED.		Wages of miners.	Wages of miners' helpers.
		Number.	Average per mine.		
Total [1]	122	5,440,952	44,598	$7,859,053	$582,765
With power drills	34	4,667,766	137,287	6,039,480	502,015
No power drills reported	88	773,186	8,786	1,819,573	80,750

[1] Michigan, Wisconsin, and Virginia not reported.

It appears that about six-sevenths of all ore produced in the 122 mines reporting came from mines equipped with power drills. The average tonnage per mine thus equipped was about fifteen times as great as the average for other mines. Miners' wages averaged $1.29 per ton for mines having power drills and $2.35 for those reporting none. On the other hand, wages of miners' helpers averaged 11 cents per ton for each class.

There were 32 mines which had no mechanical power; of these 26 were in the development stage, with a total product valued at $78,176, averaging $3,007 per mine; and 6 in the productive stage, with a total product of $121,420, averaging $20,237 per mine. There were, moreover, 9 mines which failed to report on mechanical power, presumably because they had none; their total product was valued at $141,373, averaging $15,708 per mine. This leaves a product of $50,837,067 for the 102 operators (exclusive of 1 holding company) reporting mechanical power, averaging $498,402 per mine. It is evident that the mines without mechanical power were either in the incipient stage or belonged to the type of small mines. These mines were distributed among the states and territories as follows: Arizona, 10; Colorado, 9; New Mexico, 8; Montana, 7; California and Utah, 2 each; Nevada, Virginia, and Wisconsin, 1 each.

In most of the copper mines some mechanical method was used for the transportation of the ore from the mine to the reduction works or the nearest point of shipment. Of the 122 operators reporting on this subject only 29 hauled their ore by teams, while 93, or three-fourths of the whole number, reported some mechanical method of transportation. The total length of railroad tracks reported was 55 miles on the surface and 145 miles underground, and the total number of locomotives in use was 28. Of the 55 miles of surface tracks, 5 companies owned 42 miles, as follows: In Tennessee, the Tennessee Copper Company, 11 miles, and the Ducktown Sulphur, Copper and Iron Company (Limited), 7 miles; in Arizona, the Arizona Copper Company (Limited), 10 miles, and the Detroit Copper Mining Company, 4 miles; and in Idaho, the White Knob Copper Company (Limited), 10 miles. This does not include railroads intended for general traffic. The remaining 13 miles of surface tracks were distributed among 117 mines. No reports on the subject of railroad ownership were received from the Lake Superior region and Virginia.

Water plants are an important part of the mine equipment. The reports showed 66 miles of ditches, flumes, etc., of which 42 were in Colorado, an average of more than 2 miles per mine; 8 in California, an average of more than 1 mile per mine; and 16 in all other states, making an average of 715 feet per mine.

Production.—The value of the output of copper mines was $51,178,036. This was the value at the mine of the product classed as copper ore, rough or dressed. The gross value of the copper contents of the same was $70,175,810; the total value of the copper contents of all ores mined in the United States was $71,192,014. The following table sets forth in detail the relation between these values:

TABLE 13.—*Copper contents of all ores mined, and production of copper mines, values less charges: 1902.*

Total value of copper contents of all ores mined				$71,192,014
Copper contents of gold and silver ores				1,016,204
Copper contents of copper ores				70,175,810
Production of copper mines:				
Contents of ores sold or treated and gross value of same—				
Copper	pounds	625,004,529	$70,175,810	
Gold	fine ounces	92,911	1,854,025	
Silver	fine ounces	11,452,280	5,833,256	
Lead	pounds	552,070	19,053	
Iron			22	
Increase in stock of ore, estimated value			77,792	
				77,959,958
Less:				
Treatment and freight charges			26,762,189	
Cost of purchased ores, 1,068 tons			19,733	
				26,781,922
Value at the mine				51,178,036

The value of the ore shown is computed in conformity with the customary method adopted in settlements between mine operators and smelters for gold and silver bearing copper ores. The mine operator is credited with the value of the copper and other metals contained in his ore, at a stipulated price per pound of copper, per ounce of gold and silver, etc., and he is charged a stipulated price per ton for treatment and for freight from the mine to the smelter. The difference paid to him is the value of the ore at the mine.

The price of copper averaged 11.2 cents per pound; the price of silver, about 50.9 cents per fine ounce; and gold was generally paid for at the rate of $19.95 cents per fine ounce. The usual allowance for the gold contents of the copper ore was at a round figure of $20 per fine ounce, the difference between this rate and the coining rate of $20.67 per ounce being reckoned among the charges for treatment.

The preceding table shows, among the metallic contents of the copper ore, iron valued at $22. An allowance for iron is made only on those ores which are sufficiently rich in that metal to be of value as a fluxing material.

The increase of the stock of ore represents a portion of the ore mined in 1902 which remained unsold on January 1, 1903. The value is necessarily an estimate. It applies only to the mines the ore from which was sold in crude state, the gross value and the charges being reported for the portion sold, the value of the rest being estimated on the same basis. Where the ore was dressed at the mine, or shipped to a smelter operated under joint management with the mine, it was impossible in most cases to estimate the value of the ore in the bins, the segregation of the cost of milling from other expenses being impracticable.

The increase in the stock of ore reported was 39,494 tons, or three-tenths of 1 per cent, out of a total of 11,780,064 tons mined. Evidently, as a rule, only the tonnage treated was reported. The 1,068 tons of ore purchased by the mills are taken to be a duplication of the product of some mines, which reported the value of their ores sold. Therefore the value of this ore, $19,733, is deducted from the total value reported for

1902. Yet it is possible that this ore may have come, in part at least, from mines idle in 1902. The error, if any, is a negligible quantity.

In the following table the bullion contents of the copper ores mined in 1902 are shown by states and territories:

TABLE 14.—BULLION CONTENTS OF COPPER ORES SOLD AND TREATED, BY STATES AND TERRITORIES: 1902.

STATE OR TERRITORY.	COPPER.		SILVER.		GOLD.		LEAD.		IRON.
	Pounds.	Value.	Fine ounces.	Value.	Fine ounces.	Value.	Pounds.	Value.	Value.
United States	625,004,529	$70,175,810	11,452,280	$5,833,256	92,911	$1,854,025	552,070	$19,053	$22
Arizona	121,235,546	13,351,837	612,744	311,556	15,526	310,071	431,360	15,527	22

Montana	267,779,794	30,034,912	9,675,603	4,935,070	32,153	644,178	.....	.....	.....
New Mexico	7,297,383	[1]400,318	6,048	3,021	229	4,576	.....	.....	.....
Utah	17,600,676	1,795,511	375,874	181,837	26,893	524,225	50,540	1,903	.....
Southern states[2]	12,661,328	1,356,959	11,587	3,510	120	2,240	.....	.....	.....
All other states[3]	152,583	17,834	11,083	5,574	64	1,099	8,400	294	.....

[1] The value for New Mexico is a flat value and does not include charges for smelting and freight.
[2] Includes North Carolina, Tennessee, and Virginia.
[3] Includes Idaho, Nevada, Oregon, Washington, Wisconsin, and Wyoming.

Some silver was contained in the copper ores mined in every state; but the silver contents of the Lake Superior ores were too insignificant to pay for the cost of recovering them, and, as a rule, brought no value to the owner. For the same reason no returns were made to the mine operator for the gold and silver contents of the southern ore, though some of them ultimately reached the eastern electrolytic refineries where the precious metals were saved, thus increasing the refined gold and silver product brought into the market.

The average price realized by the mine operator for the copper contents of his ore varied by states, as shown in the statement below from 5.5 cents per pound in New Mexico to 11.7 cents in Michigan. The extremely low price in New Mexico was a flat price, no charges being made for smelting and freight. The variations in other states were produced by the fluctuations of the New York price of copper in the course of the year, and depended further upon the manner in which the ore was disposed of, as will be fully explained.

Average price per pound of copper in the ore, by states and territories: 1902.

STATE OR TERRITORY.	Cents.
United States	11.2
Arizona	11.0
California	11.5
Colorado	10.0
Michigan	11.7
Montana	11.2
New Mexico[1]	5.5
Utah	10.2
Southern states[2]	10.7
All other states[3]	11.7

[1] The price for New Mexico was a flat price, from which no deduction was made for smelting and freight.
[2] Includes North Carolina, Tennessee, and Virginia.
[3] Includes Idaho, Nevada, Oregon, Washington, Wisconsin, and Wyoming.

All copper ores mined in the United States are reduced to the metallic state by smelting, some after being crushed at stamp mills and dressed, that is, cleaned of worthless rock, and thus concentrated into a smaller volume. Dressing is the universal practice in the Lake Superior district, while in western mines it is infrequent. A comparative statement of ores dressed before smelting and those shipped in crude state follows:

Method of treatment of copper ore: 1902.

	COPPER CONTENTS.			GROSS VALUE.	
	Tons of ore.	Pounds.	Per cent of crude ore.	Aggregate.	Average per ton.
Total	11,464,868	625,004,529	2.73	$70,175,810	$6.12
Dressed before smelting	[1] 6,559,397	223,935,242	1.68	25,987,738	3.89
Smelted in crude state	[2] 4,905,471	401,069,287	4.19	44,188,072	9.24

[1] The contents of 1,068 tons of ore sold by the mine operators and dressed by the purchasers are included under both heads, and to this extent constitute a duplication.
[2] The copper contents of 123,393 tons of ore smelted in crude state were included in one item with those of ore dressed before smelting.

The ore shipped from the mine directly to the smelter was of a higher grade than the average ore which had to be dressed before it could be shipped to the smelter, the average value per ton of crude ore being $9.24 for the former and $3.89 for the latter. Since, however, the dressed ores included Lake Superior copper bearing rock, which is of a much lower value than western crude ores, the latter are presented separately in the following statement:

Copper contents and gross value of western crude ores: 1902.

	COPPER CONTENTS.			GROSS VALUE.	
	Tons of ore.	Pounds.	Per cent of crude ore.	Aggregate.	Average per ton.
Total	5,144,495	441,241,136	4.29	$48,718,216	$9.47
Sold in crude state	[1] 490,248	46,612,446	4.74	4,059,618	8.26
Dressed before smelting	[1] 711,140	52,833,177	3.71	5,888,103	8.28
Smelted in crude state at works connected with mine	3,943,107	341,795,513	4.33	38,771,495	9.83

[1] Includes a duplication of the contents of 1,068 tons of ore, as explained above.

Of the 711,140 tons dressed before smelting only 39,551 tons, or 5.6 per cent, were shipped to outside smelters, the rest, after concentration, was shipped for smelting to works operated by the mine owners. The practice of dressing before smelting was confined to Arizona.

As appears from the preceding statement, the grade of ore did not vary materially with the disposition of the same. The way in which the ore was handled was apparently determined by the equipment of the mining company.

In the copper industry the combination of mining and smelting under the same operator is the predominating type of organization. The total value of the ore shipped to smelting works operated in connection with mines amounted to $40,432,863, whereas the value of the ore shipped to custom smelters was only $10,745,173. The number of mines connected with smelters was 29, and the number from which ore was shipped to custom smelters was 115. The average output per mine was $1,049,409 for the former and $93,436 for the latter.

The following table shows, by states and territories, the gross value and the metallic contents, the charges for treatment and freight and the value of the product at the mine for ores sold and for those smelted by the mine operator The Lake Superior district and the Southern states are combined to avoid disclosing items reported by individual establishments.

TABLE 15.—VALUE OF ORE SOLD AND SMELTED BY OWNER, COST OF REDUCTION, AND VALUE AT MINE, BY STATES AND TERRITORIES: 1902.

[1] Does not include $58,059, the difference between value of increase of stock on hand at close of year, having been neither sold nor smelted, and the value of ore purchased, included here but not shown in Table 1.
[2] Includes Colorado, Idaho, Nevada, New Mexico, Oregon, Washington, and Wyoming.
[3] Includes Michigan, North Carolina, Tennessee, Virginia, and Wisconsin.

The cost of reduction and freight includes all charges of any description deducted by the buyer of the ore from the gross value of the same, whenever the ore was sold, or all charges made by the smelting works against the mine whenever both were operated by the same owner. Most of the Michigan mines reported separately commissions, selling expenses, etc.; some reported separately the cost of haulage from mine to smelter.

When a mine was operated in connection with a smelter, a separate report was secured for the latter, except in one case, where the smelter was operated merely as a test for a few days. The inquiries called for the total amount paid in salaries and wages during the year 1902, the cost of supplies used during the year, and miscellaneous expenses, covering substantially the same items as indicated above; also total tolls received for custom smelting and refining, as well as total tolls paid on the product of the smelter shipped for further treatment to other smelters and refineries. In accordance with the general plan of the census of mines and quarries the expenses of the smelting works were not included among mining expenses. But when no charges were made on the books of the smelter against the mine, both being operated as one establishment, the total expenses

reported for the smelter were regarded as the cost of smelting the ores shipped from the company's mine and were deducted from the gross value of the bullion contents, in order to arrive at the value at the mine. Thus the gross value in Table 13 represents the value of the refined product, and the value at mine is that of the ore computed as herein explained. No attempt was made to estimate the profits of the operator on the smelting of the ores mined by him, as it would be purely a matter of conjecture. It was assumed that the ore was treated at cost, and the profit, if any, is therefore included in the value of the product at the mine.

When, in addition to the ores mined, custom ores were treated by the smelter, the expenses of the smelter were apportioned between the ores mined and those purchased on the basis of the tonnage, and the amount chargeable against the mine was deducted from the gross value. The total quantity of custom ores thus treated was only 447,944 tons, as compared with 7,513,269 tons shipped from mines operated under the same management, or 5.6 per cent of the total quantity treated. Thus any error in that calculation could not materially affect the results.

The value of the product at the mine, thus computed, represents the value of the ore, crude or dressed. The value of the ore at the mine shown in Table 13 differs slightly from that shown in Table 15. The difference amounts to $58,059, which is due to the omission from Table 15 of the estimated value of the increase of stock of ore, amounting to $77,792, and the inclusion of the cost of purchased ores, amounting to $19,733.

The average tenor of copper in the crude ore was 2.7 per cent or "units" of 20 pounds to the ton, and the average value per pound of copper contents was 11.2 cents; the gross value per ton on that basis averaged $6.79. Of the ores sold, nearly seven-eighths were Lake and Southern low-grade ores; taking the United States as a whole, therefore, the average percentage of copper for ore sold appears to have been less than one-half of the average for ores smelted. A comparison by states discloses a different condition; with the exception of Montana, ores shipped to custom smelters were of a higher grade than those smelted at the mine; apparently, low-grade ore could not bear the expense of shipment to a distant smelter, and could be profitably treated only at the mine. In Montana the grade of ore does not differ in the two cases, which is due to the fact that most of the mines are centered near Butte, so that the cost of transportation is not of such importance as elsewhere. The last group, combining the Lake Superior district and the Southern states, merely reflects the defects of the United States average, the reasons for which have been explained.

The average value realized per pound of copper is 1 cent less for ore sold than for ore smelted by the owner. The same relation is observed everywhere, the difference in price on Western ores varying from seven-tenths of a cent in California to 3.1 cents in Utah. The margin represents a part of the charges for the treatment of the ore. The low price reported from "other Western states" is due to the fact, as explained above, that in New Mexico ores containing 7,297,383 pounds of copper, and valued at $400,318 were sold at a flat price, no deductions being made for treatment. In the Lake Superior district the same value is allowed per pound of fine copper in the dressed ore (locally known as "mineral") and in refined bullion. The slight variation of one-tenth of a cent is due to the difference in Southern ores.

The average charges for treatment and freight must be compared by states or groups of states, inasmuch as the result for the United States is affected by the inclusion of Lake ores which are shipped to the smelter after being considerably reduced in weight by dressing. Of the total quantity of Lake ores, 5,036,547 tons were reduced to 120,042 tons of mineral—that is, to 2.4 per cent of the original weight. This method naturally reduced the cost per ton of rock treated. Compared by states the cost of treatment varies; in California and Montana, as well as in the Lake Superior district and in the Southern states, there is no apparent difference between the charges on ores sold and those smelted by the mine operator, whereas in all other Western states the cost of treatment is higher for the former than for the latter.

A segregation of the cost of reduction into charges for treatment and freight was not in all cases obtainable. The aggregate charges for reduction amounted to $26,762,189. This amount was distributed as follows:

Cost of reduction of ores: 1902.

	All ores.	Ore sold.	Ore smelted by owner.
Total	$26,762,189	$3,740,507	$23,021,682
Charges for treatment, etc.	22,124,950	2,633,857	19,491,093
Freight	3,402,359	549,260	2,853,099
Not reported separately	1,234,880	557,390	677,490

As appears from the preceding statement, 95.4 per cent of the total cost of reduction reported for ores smelted by the mine operators, and 85 per cent of the total reported for ores sold, could be segregated into freight and other charges. Freight, as far as reported, amounted to about one-sixth of the cost of reduction for ores and concentrates shipped to outside smelters, and to about one-eighth for ores smelted at works connected with the mine. The item of freight amounted, in all, to $3,402,359, which was equal to a charge of 4.4 per cent on the gross value of the ore.

Mines and mills.—When a mine and reduction works were operated under the same management, separate reports were required for each, and special schedules were provided for the purpose. Still the mine operator

was given the option of making one report covering both the mine and the reduction works, whenever it was impracticable to report them separately.

In the Lake Superior district, where ore dressing is an integral part of copper mining, the reports furnished by the mine operators included in each case both the mine and the mill. Separate reports for mine and mill were received from each of the 7 western operators. A summary of these reports is presented in the following table: .

TABLE 16.—*Summary of mines combined with mills where separately reported: 1902.*

	Mines and mills.	Mines.	Mills.
Number of mines and mills	7	7	7
Salaries	$164,517	$131,404	$33,113

Silver	$45,263	.....	.....
Gold	$25,022	.....	.....
Other metals	$15,527	.....	.....
Total gross value	$6,201,912	.....	.....

The following table is a summary of all mines that were separately reported, with and without mill connection. Lake Superior mines, as stated, do not come within this category. The table is confined to mines only; no data relating to mills are included therein.

TABLE 17.—*Summary, exclusive of mills, for mines with mill connections compared with mines not connected with mills: 1902.*

	Mines reporting.	Mines with mill connection.	Mines not connected with mills.
Number of mines	123	7	116
Salaries	$1,137,267	$131,404	$1,005,863
Wages	$12,121,518	$1,277,963	$10,843,555
Contract work	$177,043	$44,891	$132,152
Miscellaneous expenses	$862,519	$76,713	$785,806
Cost of supplies and materials	$6,271,175	$592,887	$5,678,288
Value of product at mine	$32,872,560	$3,735,811	$29,136,749
Ore mined, short tons	5,542,712	734,555	4,808,157
Ore shipped and milled:			
Short tons	5,493,218	731,699	4,761,519
Bullion contents—			
Copper—			
Pounds	453,452,464	56,920,088	396,532,376
Value	$50,055,442	$6,096,367	$43,959,075
Silver	$5,821,159	$45,263	$5,775,896
Gold	$1,854,025	$25,022	$1,829,003
Other metals	$19,075	$15,527	$3,548

Where the mine was connected with a mill the value of product reported was that of the mill product, which would not be comparable with the value reported by mines without a mill connection; the value at mine has, therefore, been estimated in the same manner as in cases where the ore was smelted at works connected with the mine; the total reported expenses of the mill have been deducted from the value of the mill product, and the difference is taken to represent the value of the crude ore at the mine. The gross value of the product is obtained by deducting the cost, $19,733, of ore purchased for the mill, from the gross value of the bullion contents; the same amount being deducted from the reported value of copper, in order to obtain the value of the copper contents of the ore mined. The value of the copper contents of purchased ore, of course, exceeded the price paid by the mill for the crude ore. Yet as the copper contents of purchased ores were less than 1 per cent of the total quantity treated, they may be regarded as a negligible quantity.

Comparison by geographic divisions.—The growth of the copper production in the United States is mainly the result of the development of copper mining in Montana and Arizona. In 1879 five-sixths of the production of the United States came from Michigan; though the annual production of Michigan has since more than trebled, the relative share of Michigan had declined to a little over one-fourth in 1902, while the output of Montana and Arizona for the year 1902 amounted to nearly three-fifths of the production of the United States. The copper production of the above three states and of the United States since the year 1883 when records for Montana and Arizona began, is presented in the following table:

TABLE 18.—*Production of the United States, and of the Lake Superior, Montana, and Arizona districts: 1883 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

[Long tons.]

YEAR.	Total production, United States.	LAKE SUPERIOR.		MONTANA.		ARIZONA.	
		Production.	Per cent of total.	Production.	Per cent of total.	Production.	Per cent of total.
1883	51,574	26,653	51.6	11,011	21.3	10,658	20.7
1884	64,708	30,961	47.8	19,256	29.8	11,935	18.4
1885	74,052	32,209	43.5	30,267	40.9	10,137	13.7
1886	70,430	36,124	51.3	25,362	36.0	6,990	9.9
1887	81,017	33,941	41.9	35,133	43.4	7,910	9.7
1888	101,054	38,604	38.2	43,704	43.2	14,195	14.0
1889	101,239	39,364	38.7	43,849	43.3	13,654	13.5
1890	115,966	45,273	38.9	50,437	43.5	15,534	13.4
1891	126,839	50,992	40.2	50,028	39.5	17,800	14.0
1892	154,018	54,999	35.7	72,860	47.3	17,160	11.1
1893	147,033	50,270	34.2	69,290	47.1	19,200	13.1
1894	158,120	51,031	32.3	81,729	51.6	19,873	12.6
1895	169,917	57,737	34.0	84,900	50.0	21,408	12.6
1896	205,384	64,073	31.2	99,071	48.2	32,560	15.8
1897	220,571	64,858	29.4	102,807	46.6	36,398	16.5
1898	235,050	66,291	28.2	92,041	39.2	49,624	21.1
1899	253,870	65,803	25.9	100,503	39.6	59,399	23.4
1900	270,588	64,938	24.0	120,865	44.7	52,820	19.5
1901	268,782	69,772	25.9	102,621	38.2	58,383	21.7
1902	294,423	76,165	25.9	128,975	43.8	53,547	18.2

A comparative summary by geographic divisions is presented in Table 19. The Lake Superior district is practically synonymous with the state of Michigan; the returns of the present census of mines and quarries show only 1 small mine in Wisconsin, with an output valued at less than $500.

TABLE 19.—*Comparative summary of western, Lake Superior, and southern copper mines: 1902.*

	Western states.	Lake Superior district.	Southern states.
Number of mines	118	25	5
Salaries	$1,106,056	$598,076	$64,324
Wages	$12,212,957	$8,745,204	$193,244
Contract work	$177,043	$11,725	----
Miscellaneous expenses	$859,031	$474,446	$63,988
Cost of supplies and materials	$6,293,251	$4,688,419	$101,505
Value of product at mine	$32,206,884	$18,247,417	$665,676
Ore mined, short tons	5,186,183	6,247,352	346,529
Ore shipped and milled:			
Short tons	5,145,563	5,971,650	348,723

Average return from by-products:			
Per ton mined	$1.48	$0.002	$0.017
Per ton sold and treated	$1.49	$0.002	$0.016
Per pound of copper, cents	1.7	----	----

Lake Superior district.—Until the development of copper mining in the Western states, in the early eighties, the Michigan mines were practically the only source of domestic production of copper. A comparative summary of census statistics for Michigan copper mines beginning with 1860 is presented in the following table:

TABLE 20.—*Comparative summary, Michigan: 1860 to 1902.*

	1902	1889	1880	1870	1860
Number of mines	20	(1)	19	[2] 27	[2] 30
Salaried officials, clerks, etc.:					
Number	419	[3] 41	(4)	(4)	(4)
Salaries	$598,076	$67,369	(4)	(4)	(4)
Wage-earners:					
Average number	13,887	[3] 5,695	5,190	4,188	3,631
Wages	$8,744,892	$3,174,363	$2,661,243	$2,346,535	$1,388,208
Contract work	$11,725	$306,627	----	----	----
Miscellaneous expenses	$473,501	$1,247,978	(1)	(1)	(1)
Cost of supplies and materials	$4,688,419	$2,682,491	$1,215,206	$555,416	$139,600
Product:					
Pounds of copper	171,102,065	87,455,675	45,830,262	(1)	(1)
Value	$20,563,353	(1)	$7,979,232	$4,312,167	$2,282,182

[1] Not reported.
[2] Establishments.
[3] Foremen included in wage-earners.
[4] Not reported separately.

The noteworthy feature disclosed by the preceding table is the gradual concentration of production from one census to another. Assuming that the establishments reporting in 1860 and 1870 represented mines, the number of mines decreased from 1860 to 1880, and since then has remained about the same; but the output at each census has been about double the value or the quantity reported at the preceding census. The average production per mine was as follows: In 1860, $72,379; in 1870, $159,710; in 1880, $419,960; and in 1902, $1,028,168.

The progress in the equipment of mines went on in proportion to the increase in the volume of production. This is illustrated by the growth of the number and horsepower of steam engines used, as summarized in the following statement:

Steam engines and horsepower in Michigan: 1902, 1880, and 1870.

YEAR.	Number of mines.	NUMBER OF ENGINES.		HORSEPOWER.		
		Total.	Average per mine.	Total.	Average per engine.	Average per mine.
1902	20	439	22.0	137,522	313	6,876
1880	19	113	5.9	12,715	112	669
1870	[1] 27	86	3.2	5,943	69	220

[1] Establishments.

The preceding statement clearly shows the remarkable growth of the application of steampower, especially within the last two decades. The average power employed in the production of 1 short ton of fine copper in 1880 was equal to fifty-five hundredths of 1 horsepower, and in 1902 to 1.61 horsepower, nearly threefold.

Of the 20 mines reporting in 1902, 13 made complete reports, stating the quantity of rock treated, the quantity of mineral produced, and the fine copper contents of the mineral; 3 failed to state the quantity of rock treated, but reported the quantity of mineral and copper contents; 4 reported the quantity of rock treated and the fine copper contents, but failed to report the quantity of mineral produced. The total reported quantity of rock hoisted was 6,247,317 tons, of which 5,971,615 tons were treated and 275,702 tons, or 4.4 per cent, were rejected as too poor to go to the stamp mill.

Complete reports from 13 mines showed 5,036,547 tons treated at stamp mills, with a yield of 240,084,170 pounds of mineral, containing 144,217,300 pounds of fine copper. The rock was reduced by treatment to 2.4 per cent of its weight; the fine copper contents averaged 60.1 per cent of the mineral, or 1.4 per cent of the weight of the rock. Returns from 16 mines showed 5,971,615 tons of rock treated, containing 165,631,605 pounds of fine copper, or 1.4 per cent of the quantity of ore treated. Returns from 17 mines showed 249,569,244 pounds of mineral, yielding 149,262,636 pounds of fine copper, or 59.8 per cent.

The percentage of mineral produced varied in individual cases from six-tenths of 1 per cent to 2.4 per cent of the rock treated, and the copper contents varied from 53.4 per cent to 91 per cent of the mineral. The proportion of 2.4 per cent of mineral to the quantity of rock treated and 60 per cent for the fine copper contents of the mineral, or 1.4 per cent for the fine copper contents of the rock, may be taken as representing the general average. Upon this basis the quantity of rock treated in cases where mineral alone was reported may be estimated at 198,000 tons, which would raise the quantity reported to about 6,179,000 tons, or 3.2 per cent.

The total quantity of rock hoisted in 1889 was 2,363,733 tons, of which 2,137,653 tons were treated, a part of the ore being rejected as too poor to go to the stamp

mill. This quantity of ore yielded 117,804,926 pounds of mineral, or an average of 2.8 per cent. The average percentage of fine copper in the mineral was 74.2 per cent.

The progress of copper mining in the Lake Superior district is shown in the following statement:

Production and dividends of Lake copper mines, by quadrennial periods: 1879 to 1902.[1]

PERIOD.	Quantity of fine copper (pounds).	GROSS VALUE.		DIVIDENDS.		Average gross value per pound, less dividends per pound (cents).
		Total.	Average per pound (cents).	Amount.	Average per pound (cents).	
1879–1882	204,094,755	$37,769,141	18.5	$10,413,620	5.1	13.4
1883–1886	282,121,955	35,683,232	12.6	7,867,500	2.8	9.8
1887–1890	352,086,633	50,755,245	14.4	10,715,000	3.0	11.4
1891–1894	464,335,117	49,963,618	10.8	12,700,000	2.7	8.1
1895–1898	562,056,573	63,996,758	11.4	19,553,250	3.5	7.9
1899–1902	615,920,822	95,929,592	15.6	33,066,550	5.4	10.2
1899–1901	444,818,757	75,829,167	17.0	29,626,550	6.7	10.3
1902	171,102,065	20,100,425	11.7	3,440,000	2.0	9.7

[1] Compiled from the Copper Handbook, Vol. III, page 573.

In the statement which follows all Lake Superior copper companies are divided into three classes: (1) Those whose total dividends since organization have more than equalled the amount of capital stock issued, (2) those whose dividends have not equalled the amount of capital stock issued, and (3) those which have never paid any dividends.

Capital stock issued and total dividends paid since organization by Lake Superior mining companies.[1]

	Number of companies.	Stock issued.	Dividends paid.
Total	60	$46,038,500	$117,685,920
Dividends in excess of stock issued	10	5,122,000	116,045,920
Dividends short of stock issued	6	3,987,500	1,640,000
No dividends paid	44	36,929,000	.....

[1] The Copper Handbook, Vol. III, page 592.

The large majority of the Lake Superior copper mining companies have never paid any dividends. Of the 16 dividend paying companies 4 were absorbed by other companies, 2 of which were themselves dividend paying; 2 were closed after a successful career; 1 was closed after earning in eleven years enough to retire its outstanding capital stock; and 1 was closed after proving a losing venture. This leaves 10 active dividend paying companies, of which, however, only 3 paid dividends in 1902. The total number of active companies reported to the census of 1902 was 20; it is therefore apparent that 10 of this number had never paid any dividends. Of the 44 companies which at one time or another have operated in the Lake Superior region 34 were inactive or did not exist during the census year. The 2 mines mentioned above which closed after proving profitable investments were Cliff, which from 1849 to 1867 netted in dividends $2,407,620, after earning an amount equal to its capital stock of $111,000, and Central, which from 1864 to 1891 netted in dividends $1,870,000, after earning an amount equal to its capital stock of $100,000.

A very instructive record of mining for a long series of years is presented in the published reports of the Quincy Mining Company. It was organized in 1848 and reincorporated in 1878 with a capital stock of $2,500,000, and had paid in dividends since organization to the close of 1902, $13,920,000. The company operated its own smelter in connection with its mine, and marketed refined copper. The statistics are given in the following statement:[1]

Quincy Mining Company: 1866 to 1902.

YEAR.	Product (pounds).	Yield of fine copper per fathom broken (pounds).	Price obtained per pound (cents).	Cost per pound exclusive of construction (cents).	Number of miners.	Average monthly contract wages.
1866	2,114,220	451	31.3	29.0	227	$53.16
1867	1,921,620	526	22.7	18.9	167	50.83
1868	1,417,941	447	25.2	23.1	157	50.44
1869	2,417,365	446	21.9	16.7	210	51.10
1870	2,496,774	528	21.5	15.3	181	46.09
1871	2,409,501	441	22.8	15.2	104	47.08
1872	2,269,104	391	32.5	22.9	233	60.62
1873	2,621,087	491	26.5	18.6	223	62.42
1874	3,050,154	577	21.9	15.1	234	43.38
1875	2,798,281	485	22.7	15.8	217	46.74
1876	3,073,171	507	20.0	15.7	227	47.13
1877	2,837,014	467	18.6	15.1	247	43.79
1878	2,991,050	395	14.9	14.0	234	41.50
1879	2,639,958	408	16.3	13.7	212	38.76
1880	3,609,250	563	18.5	11.8	192	49.10
1881	5,702,606	766	18.7	10.6	212	48.54
1882	5,682,663	800	17.1	9.5	152	48.83
1883	6,012,239	850	13.7	8.9	165	46.02
1884	5,680,087	722	12.2	8.6	157	43.35
1885	5,848,497	710	11.4	7.5	132	44.00
1886	5,888,517	638	11.1	6.8	140	45.80
1887	5,603,691	781	11.7	8.6	142	48.40
1888	6,367,809	690	15.9	10.1	158	49.60
1889	6,405,686	690	12.0	9.4	145	49.15
1890	8,064,253	769	15.7	8.2	146	52.60
1891	10,542,519	685	12.8	9.1	182	53.40
1892	11,103,926	572	11.2	8.8	238	53.75
1893	14,398,477	574	10.4	7.1	259	49.60
1894	15,484,014	584	9.5	5.7	285	50.70
1895	16,304,721	517	10.1	5.9	336	50.00
1896	16,863,477	477	10.0	6.5	379	52.00
1897	16,924,618	481	11.1	6.8	393	52.52
1898	16,354,061	513	12.0	6.8	381	52.50
1899	14,301,182	427	17.0	8.1	401	56.72
1900	14,116,551	391	16.6	9.3	433	62.00
1901	20,540,720	409	16.1	8.8	533	62.00
1902	18,988,491	347	12.0	9.0	562	62.00

The preceding statement shows that the average annual production of the company increased after 1866 nearly tenfold, whereas the average number of miners employed increased about 2½ times—that is, the average miner is able to produce with modern methods and machinery about four times as much as in 1866. The cost of production per pound has been reduced to less than one-third of what it was in 1866.

Montana, Arizona, and New Mexico.—Copper mining in Montana, Arizona, and New Mexico did not develop until the eighties. Very scant information on copper mines in that region is recorded in the reports of the Tenth Census. Arizona reported 110 wage-earners whose wages aggregated $77,128. The production did

[1] For 1866 to 1901, taken from the Copper Handbook, Vol. III, pages 458 and 459; for 1902, from the report of the company.

not exceed 7,650 tons of ore, which contained 3,183,750 pounds of copper.

Montana reported in 1880 only 523 tons of ore containing 1,212,500 pounds of copper, and New Mexico had only 13 tons to show, which yielded 4,055 pounds of copper.

A comparative summary for the years 1902 and 1889 follows:

TABLE 21.—COMPARATIVE SUMMARY FOR ARIZONA, MONTANA, AND NEW MEXICO: 1902 AND 1889.

	Year.	SALARIED OFFICIALS, CLERKS, ETC.		WAGE-EARNERS.		Contract work.	Miscellaneous expenses.	Cost of supplies and materials.	PRODUCT.		
		Number.	Salaries.	Average number.	Wages.				Tons of ore.	Copper contents. Pounds.	Copper contents. Per cent ratio per ton.
Arizona	1902	258	$399,275	3,797	$3,497,528	$122,337	$256,753	$2,135,676	1,210,301	121,235,546	5.01
	1889	14	23,762	838	726,021	23,774	48,242	325,020	155,586	31,362,685	10.08
Montana	1902	310	494,415	6,388	7,339,773	40,975	456,108	3,649,127	3,428,860	267,779,794	3.90
	1889	10	22,515	1,948	2,010,940	2,722	138,288	1,029,990	698,837	97,868,064	7.00
New Mexico	1902	24	32,120	164	128,483	10,266	26,858	49,408	46,993	7,297,383	7.76
	1889	5	7,250	240	184,701	1,320	8,338	30,469	34,586	3,883,014	5.61

The average copper contents per ton of ore mined in Montana and Arizona has considerably decreased since 1889. It may be inferred from these figures that the development of those parts of the country, and the introduction of improved processes, have made it possible to treat lower grades of ore, which could not have been profitably worked in 1889.

Smelters connected with mines.—The following table is a summary for smelters connected with mines; the expenses shown therein (salaries and wages, miscellaneous expenses, supplies and materials) are not included in the statistics of copper mines, having been used merely in estimating the value of the ore at the mine as explained on a previous page, under the head of "production."

TABLE 22.—SUMMARY OF SMELTERS AND REFINERIES CONNECTED WITH MINES: 1902.

CHARACTER OF SMELTING WORKS.	Number of establishments.	Salaries and wages.	Miscellaneous expenses.	Supplies and materials, not including ores.	Cost of refining.	Freight on bullion shipped.	MATERIALS TREATED. Ore from mine (short tons).	MATERIALS TREATED. Purchased ore (short tons).	Purchased matte (short tons).	Copper produced (pounds).
Total	29	$8,796,932	$2,156,205	$9,033,227	$1,961,001	$1,536,788	4,161,772	411,029	36,915	557,111,390
Treating ore from mine only	16	2,322,779	321,351	2,466,770	954,316	984,819	958,255	.....	.....	166,483,274
Treating ore mined by company and purchased ore	7	1,715,338	98,858	1,732,249	981,016	511,675	811,677	162,208	17,248	112,245,520
Connected with refinery	6	4,758,815	1,735,996	4,834,208	25,669	40,294	2,391,840	248,821	19,667	278,382,596

The summary is not intended as a complete presentation of the business transacted by the smelters, which is beyond the scope of the census of mines and quarries. The cost of purchased ores is therefore not included in the statement, nor are the earnings from the treatment of custom ores given therein. Copper smelters located in Michigan are not comprised in this statement. It includes, however, the Buffalo smelter of the Calumet and Hecla Mining Company, to which a portion of its product is shipped for treatment.

The copper product shown contains a duplication of 11,808,230 pounds, representing the contents of matte produced by one of the smelters and further treated at two of the six smelters and refineries included in the summary. The total copper product of these smelters was accordingly 545,603,160 pounds.

Copper contents of all ores mined, including gold and silver ores.—The production discussed in the preceding pages is that which is credited to the copper mines, as therein defined. For certain comparative purposes it is necessary to show the copper contents of all ores mined, including those whose chief value is that of their precious metal contents. The following statement shows the copper contents of all ores mined in 1902, by sources of production:

Copper contents of all ores mined, by sources of production: 1902.

SOURCE OF PRODUCTION.	Pounds.	Gross value at mine.
Total	639,033,392	$71,192,014
Copper mines	625,004,529	70,175,810
Gold and silver mines	14,028,863	1,016,204

The share contributed by each state or territory to the copper production of the United States is shown in the following table:

TABLE 23.—*Copper contents of all ores mined, by states and territories: 1902.*

STATE OR TERRITORY.	Pounds.	Value.
United States	639,033,392	$71,192,014
Arizona	121,409,275	13,367,135
California	26,549,063	3,055,908
Colorado	5,841,074	450,355
Georgia	9,500	1,235
Idaho	86,442	9,149
Michigan	171,102,065	20,100,425
Montana	268,440,090	30,092,781
Nevada	29,114	3,134
New Mexico	8,017,902	462,053
North Carolina	418,801	45,531
Oregon	46,154	2,800
South Dakota	787	67
Tennessee	12,284,515	1,316,991
Utah	24,720,824	2,272,692
Virginia	3,246	398
Washington	72,540	10,890
Wisconsin		210
Wyoming	2,000	260

Consumption of copper ores.—In order to verify the accuracy of the returns for the production of copper mines, they must be compared with the reports of all copper smelters showing the consumption of copper ores as materials for smelting.

With that purpose in view the special schedule relating to copper mines contained an inquiry calling for the name and address of the mill or works at which the ore was treated. The special schedule provided for mills ("reduction works other than smelters") called for the "name, location, and character of establishment to which the product was sold or shipped for final treatment." A similar inquiry was inserted in the special schedules addressed to smelters. These inquiries were intended to trace the product from the producer to the consumer, as well as to guard against duplications in cases where the same product was successively treated by different establishments.

Only 4 mines failed to answer the inquiry. The total production of those mines was 257 tons of ore, containing 20,604 pounds of copper, having a gross value of $2,212; in a total production of copper the gross value of which exceeded $70,000,000, this is a negligible quantity.

Copper ore mined in the United States is eventually converted into metallic copper in this country, with the exception of a small quantity exported in the shape of matte. Matte (called also "regulus") is a semi-metallic product obtained from ore by fusion; it contains from 25 to 70 per cent of copper and is blown by further fusion to metallic copper.

A portion of the ore was thus concentrated at local matte smelters and shipped for further treatment to other smelters which produce pig copper. The total fine copper contents of matte shipped, according to reports received at the Bureau of the Census, amounted to 43,339,268 pounds. Of this quantity, 6,717,594 pounds were shipped to New York brokers for export; 13,325,690 pounds were traced from the matte smelters to the plants where the matte was converted into metallic copper; 22,977,984 pounds were reported by copper smelters as the contents of purchased matte, the producers of the matte failing to report; and 319,000 pounds were reported by shippers, the destination of the matte not being stated.

The copper contents of the matte, with the exception of the 13,325,690 pounds which were reported by both shippers and buyers, must be included in the total output of copper. The 319,000 pounds reported only by shippers were either intended for export, or they may have been duplicated in the report of some other smelter. Compared with the total production of the United States, the error would amount to only five-hundredths of 1 per cent.

The production of matte and metallic copper, as reported by smelters, is shown in the statement below.

The Lake Superior ores were smelted at the following works: The output of the Calumet and Hecla Mining Company and the Quincy Mining Company at their own smelters, from which reports were secured; the mineral from all other mines was treated by the Quincy Mining Company and by the Lake Superior Smelting Company, at Hancock, Mich. No report was secured from the latter. The copper product of Lake Superior ores has, therefore, been taken from the reports of the Michigan mining companies, including the two above named, which had their own smelters.

Some copper was produced by lead smelters engaged principally in the treatment of gold and silver bearing ores; the quantity reported by them is shown separately in the following statement:

Production of metallic copper and matte in the United States: 1902.

Metallic copper:	Fine copper (pounds).
From—	
Western and southern ores	424,721,738
Lake Superior ores	171,102,065
Imported ores	40,797,847
Reported by lead smelters	18,931,168
Matte	43,339,268
	698,892,086
Deduct duplication in matte	13,325,690
Total output of smelters	685,566,396
Less product of imported ores	40,797,847
Total copper product of all domestic ores	644,768,549
Reported by mine operators	[1] 639,033,392
Variance	5,735,157

[1] Includes 14,028,863 pounds reported as by-product of gold and silver ores.

The variance between the output of mines and smelters is less than 1 per cent.

The United States Geological Survey reports the total output of copper refineries as 699,508,644 pounds, and estimates the copper contents of imported ores at 40,000,000 pounds; the difference, 659,508,644 pounds, is taken to represent the copper production of the United States for 1902. This estimate exceeds the production of mines by 20,475,252 pounds, or 2.9 per cent, and the output of smelters by 15,340,155 pounds, or 2.4 per cent.

There naturally would be a difference between the copper contents of ore shipped from the mines and the quantity of copper produced by smelters and refineries. Where the ore was smelted by the mine operator the quantity reported, as a rule, represented the actual recovery of fine copper; but where the ore was shipped to a custom smelter the quantity reported represented the assay contents which were paid for. Furthermore, the periods covered by the returns were not in all cases the same, some companies reporting for their various fiscal years nearest to the calendar year 1902. Then, too, the stocks on hand and in process carried at the smelters and refineries fluctuate from one year to another. In one case reported to this office the deliveries of an electrolytic copper refinery for 1902 differed from the receipts for the same year by more than 40,000,000 pounds of fine copper. Again, duplications can not always be avoided. That the variance between the quantities reported for the several stages of the copper industry is confined within such narrow limits vouches for the substantial accuracy of the results.

Mineral lands.—The primary distinction between mining and manufacturing is that in the former industry there are three factors of production, viz, land, capital, and labor, while only labor and capital are essential in the latter. The present census of mines and quarries is the first in which the scope of the inquiry has in some branches been extended to the ownership of mineral lands. Though the special schedule provided for gold, silver, lead, and copper mines was confined to mineral lands, it is probable that in some cases the reports included all lands of any description, such as timber lands, building lots, etc.

The following table shows the distribution of mineral lands, by title of tenure, for the United States and by states and territories. For 5 of the 144 mines no report was made on this subject—3 in Arizona, 1 in New Mexico, and 1 in Virginia; 1 establishment was a holding company.

TABLE 24.—*Summary of mineral lands, by states and territories: 1902.*

STATE OR TERRITORY.	Total acres.	LAND OWNED.		LAND LEASED.	
		Number of mines.	Acres.	Number of mines.	Acres.
United States	86,523	[1]122	83,270	[1]20	3,253
Arizona	13,754	27	13,754	.....	.....
California	6,120	6	5,960	1	160
Colorado	1,664	14	1,422	4	242
Idaho	544	1	544	.....	.....
Michigan	39,281	20	39,281	.....	.....
Montana	2,572	23	2,306	4	266
Nevada	200	1	200	.....	.....
New Mexico	4,478	10	3,895	6	583
North Carolina	2,357	2	1,257	1	1,100
Oregon	1,400	2	1,400	.....	.....
Tennessee	11,600	2	10,750	1	850
Utah	1,088	11	1,056	2	32
Washington	800	1	800	.....	.....
Wisconsin	320	1	320	.....	.....
Wyoming	345	1	325	1	20

[1] Of this number 4 mines reported both owned and leased land.

Of the acreage owned, as shown in the preceding table, 91 acres were reported by the owners as leased to other parties, viz, 16 acres in Montrose county, Colo., on which copper was not mined, and 75 acres distributed among other states and territories, upon which miners were virtually employed on a share of the product, as explained on a previous page. In the above table, consequently, these 91 acres are not duplicated.

The leasing of land apparently plays a very subordinate part in copper mining. The royalties on the 3,253 acres leased aggregated $33,184, or a little over $10 per acre. The greater part of the acreage, namely, 2,080 acres, was held by 4 operators, who, in addition to leased land, operated their own mines and made in each case only one report for the entire operation. A summary for those mines which were operated exclusively on leased land is presented in the following table:

TABLE 25.—*Number of mines operating exclusively on leased lands, acres leased, value of product, and royalties paid: 1902.*

STATE OR TERRITORY.	Number of mines.	Acreage leased.	Value of product at mine.	Royalties paid.
United States	16	1,173	$85,103	$21,291
Colorado	4	242	1,620	360
Montana	4	266	29,955	7,579
New Mexico	5	473	49,014	11,508
All others[1]	3	192	4,514	1,844

[1] Includes California, 1; Utah, 2.

The mines operated on leased land were all very small producers; a little over one-half of that land, viz, 652 acres, was still under development. The royalties paid amounted to about one-fourth of the value of the product at the mine.

In the following table all mines are classified by the area of mineral lands owned and leased:

TABLE 26.—ACREAGE OF MINERAL LANDS, BY STATES AND TERRITORIES: 1902.

STATE OR TERRITORY.	TOTAL.		20 ACRES OR LESS.		21 TO 99 ACRES.		100 TO 999 ACRES.		1,000 TO 4,999 ACRES.		5,000 ACRES AND OVER.

Utah	13	1,088	3	52	6	268	4	768				
Washington	1	800					1	800				
Wisconsin	1	320					1	320				
Wyoming	1	345					1	345				

The correlation between ownership of land and value of production is shown in the following table:

TABLE 27.—*Acreage owned and leased, and value of product: 1902.*

SIZE OF HOLDING.	Number of mines.	AREA.		VALUE OF PRODUCT AT MINE.		AVERAGE VALUE.	
		Acres.	Per cent.	Amount.	Per cent.	Per mine.[1]	Per acre.[2]
Total	144	86,523	100.0	$51,178,036	100.0	$357,888	$586
Less than 100 acres	54	1,647	1.9	5,926,937	11.6	109,758	3,599
100 to 999 acres	59	17,345	20.0	20,963,808	40.9	355,319	1,209
1,000 to 4,999 acres	23	48,861	56.5	23,622,384	46.2	1,027,060	483
5,000 acres and over	3	18,670	21.6	164,951	0.3	54,984	9
Acreage not reported	[3]5			499,956	1.0	124,989	

[1] This average is computed only for mines reporting product.
[2] This average is computed only for mines reporting acreage.
[3] Includes one holding company.

It appears that the value of the production of the mines bore no close relation to the area of mineral lands owned or leased. Still the average value of production per mine increased with the increase in the area of mineral lands owned up to 5,000 acres, though not in the same ratio.

The average value of production per acre decreased as the area increased and the three largest owners were among the smallest producers. It is probable that while the smaller properties were under active operation the larger were awaiting development.

Concentration of the industry.—Copper mining is a highly centralized industry, as appears from the following tables. Table 28 shows the acreage of all mineral lands by districts.

TABLE 28.—ACREAGE OF MINERAL LANDS, BY DISTRICTS: 1902.

	TOTAL.		20 ACRES OR LESS.		21 TO 99 ACRES.		100 TO 999 ACRES.		1,000 TO 4,999 ACRES.		5,000 ACRES AND OVER.	
	Number reporting.	Acreage.	Number reporting.	Acreage.	Number reporting.	Acreage.	Number reporting.	Acreage.	Number reporting.	Acreage.	Number reporting.	Acreage.
United States	139	86,523	28	340	26	1,307	59	17,345	23	48,861	3	18,670
Western states	114	32,965	28	340	26	1,307	54	14,285	5	12,033	1	5,000
Lake Superior district	21	39,601					5	3,060	15	31,541	1	5,000
Southern states	4	13,957							3	5,287	1	8,670

The preceding table clearly illustrates the degree of concentration in the ownership of mineral lands; 78 per cent of the entire area was held by 26 companies, of which 16 were in the Lake Superior district. In the Southern states there were no mining properties of less than 1,000 acres; in the Lake Superior district only 5 held less than 1,000, the average for these being 612 acres. All small mines were located in the Western states, where the concentration was less pronounced.

Table 29 shows the classification of all copper mines of the United States by value of production.

TABLE 29.—*Classification of copper mines by value of production: 1902.*

GROUP BY VALUE.	Number in each group.	VALUE OF PRODUCT AT MINE.	
		Amount.	Per cent.
Total	144	$51,178,036	100.00
Less than $500	21	4,015	0.01
$500 to $999	9	6,523	0.01
$1,000 to $9,999	44	155,552	0.30
$10,000 to $49,999	25	578,766	1.13
$50,000 to $99,999	6	379,162	0.74
$100,000 to $249,999	8	1,160,687	2.27
$250,000 to $499,999	8	3,265,037	6.38
$500,000 to $999,999	11	8,171,374	15.97
$1,000,000 and over	12	37,456,920	73.19

As seen from the preceding table, about three-fourths of the output was contributed by 12 mines producing over $1,000,000 each, and only about one-ninth by 121 mines producing less than $500,000 each.

A similar classification by geographic divisions is impossible without disclosing the individual returns of some mine. It may be stated, however, from an examination of the statistics of production arranged by states, in the same manner as above, that the same proportions shown in the table obtain, with but slight variations, in Montana, Arizona, and the Lake Superior district, which furnish together 92 per cent of the production of the United States. The mines located in other states ranged, according to their output, as follows: 1 over $1,000,000; 1 over $500,000, but less than $1,000,000; 2 over $250,000, but less than $500,000. The output of these 4 mines was valued at $2,928,958, or 71.6 per cent of the total product of these states. There were, moreover, 62 mines distributed as follows: 6 producing over $100,000, but less than $250,000 each, with an aggregate output of $819,661, or 20.1 per cent of the total; 11 producing more than $10,000, but less than $100,000 each, with an output of $269,839, or 6.6 per cent; and 45 producing less than $10,000 each, with an aggregate output of $69,584, or 1.7 per cent.

The preceding statistics, dealing as they do with individual mines or operating companies as units, do not fully express the actual degree of concentration which manifested itself in a variety of forms. One holding company, the Amalgamated Copper Company, controlled, through the ownership of stock, 6 copper mining companies in Montana. The combined production of these companies for the year ending June 1, 1903, according to their sworn statements filed with the assessors of Silverbow county, Mont., aggregated 3,140,380 tons of ore, having a gross value of $33,635,176. Compared with the total production of the copper mines of the United States, as reported at the census of 1902, or for the fiscal year nearest to the same, the output of the Amalgamated Copper Company constituted 27.4 per cent of the tonnage and 43.1 per cent of the gross value.

Closely allied with the Amalgamated Copper Company was the Tennessee Copper Company, whose directorate included two of the directors of the former. Its mining properties situated in Tennessee produced in 1902, according to the report of the directors to the stockholders, 8,103,534 pounds of copper, gross value, $1,024,450, which amounted to 1.3 per cent of the gross value of the output of all copper mines, as reported to the Bureau of the Census.

Next in importance after the Amalgamated Copper Company was the Calumet and Hecla Copper Company of Michigan. President Alexander Agassiz reported for the fiscal year ending April 30, 1903, a production of 38,316 long tons of fine copper, equal to 85,827,840 pounds.[1] The fine copper contents of the copper ores treated in the United States in 1902, as reported to the Bureau of the Census, amounted to 625,004,529 pounds. The production of the Calumet and Hecla Copper Company accordingly approximated 14 per cent of the total output of the copper mines of the United States.

The third place was held by the United Copper Company, which was organized in Montana under the corporate name of the Montana Ore Purchasing Company. The latter reported to the assessors of Silverbow county, Mont., for the fiscal year ended June 1, 1903, an output of 293,332 tons of ore having a gross value of $3,587,692. Mr. F. Augustus Heinze, president of the company, made the following statement to the press regarding the production of the company:

Production of the United Copper Company: 1902 and 1901.[1]

YEAR.	Copper (pounds).	Silver (ounces).	Gold (ounces).
1902	30,374,696	919,590	11,269
1901	30,318,228	1,083,474	4,631

[1] The Commercial and Financial Chronicle, Vol. 76, pages 870 and 927.

Compared with the output of the copper mines of the United States, the production of the United Copper Company constituted 4.6 per cent of the total gross value, or 4.8 per cent of the fine copper contents.

An important group of mines was represented by 7 Michigan companies, which, though maintaining a separate corporate existence, were united under a common management through the ownership of the stock by the same group of stockholders. These were the Winona Copper Company, the Wolverine Copper Mining Company, the Mohawk Mining Company, the Atlantic Mining Company, the Baltic Mining Company, the Michigan Copper Company, and the Champion Copper Company. The total output of these companies, as shown in their published reports, yielded 25,237,594 pounds of fine copper having a gross value of $2,992,335, and constituted 4 per cent of the fine copper contents, or 3.8 per cent of the gross value reported at the census of 1902 for all copper mines.

The respective shares contributed by the above-named companies to the production of the United States are shown in the following statement:

Percentage production of eleven companies formed of total: 1902.

COMPANY.	Per cent of the output of United States.
Total	67
Amalgamated Copper Company	43
Tennessee Copper Company	1
Calumet and Hecla Copper Company	14
United Copper Company	5
Seven Michigan companies	4

[1] The Commercial and Financial Chronicle, Vol. 77, page 193.

This list is not exhaustive; it does not include the United Verde Copper Company of Arizona and the Colusa-Parrott Copper Company of Montana, which are controlled by the same interests, and probably some other mines for which there are no available data. The properties enumerated in the preceding statement contribute two-thirds of the output of the United States.

The possibilities for further centralization are indicated by the location of the general offices of the mining companies. Of the 144 mines, 49 had their offices in the East—31 in New York and 18 in Boston. The output of these mines aggregated 463,445,212 pounds of copper out of a total output of 639,033,392 pounds; that is, 72 per cent of the production of the United States.

During the years 1900, 1901, and 1902, the output of the principal copper producers was handled by a joint selling agency—the United Metals Selling Company. This company was organized on January 29, 1900, and included among its incorporators two representatives of interests identified with the Amalgamated Copper Company. Its patronage, however, was not confined to that company alone. The company's charges were from 1.5 to 2.5 per cent for selling copper. Its total sales for 1902 were estimated by the Boston News Bureau at 545,000,000 pounds,[1] which amounted to 83 per cent of the output of refined copper for the year, as estimated by the United States Geological Survey.

In 1892 an association of copper producers, known as the American Producers' Association, was formed. It represented the following mines: Montana district, those of the Amalgamated Copper Company; Arizona district—Verde, Arizona, Queen, Detroit, Dominion; Lake Superior district—Calumet, Tamarack. Quincy, Osceola, Atlantic, Franklin, Tamarack, jr., Kearsarge, Wolverine, and Central.[2] Other companies joined the association subsequent to the date on which that list was compiled.[3] The association received from its members reports of the production of copper, which were compiled and published monthly. The production of the mines affiliated, as well as of those outside the association as contained in these reports, is shown in the following comparative statement:

American production of copper, as reported by the American Producers' Association: 1892 to 1902.

[Long tons.]

YEAR.	Total.	Reporting mines.	Outside sources.
Second six months of 1892	65,526	59,239	6,287
1893	142,490	129,760	12,730
1894	159,623	142,543	17,080
1895	171,197	155,497	15,700
1896	203,894	189,494	14,400
1897	216,106	204,206	11,900
1898	234,272	216,222	18,050
1899	262,206	230,806	31,400
1900	268,787	227,987	40,800
1901	265,255	223,355	41,900
1902	295,656	258,056	37,600

Early in 1903 large producing interests withdrew from the American Association, declining to furnish statistics, so that the monthly compilations have ceased.

It is worthy of note that the centralizing tendency in the operation of copper mines has been accompanied by a growing decentralization of property interests. This clearly appears from the following statement of the number of stockholders of copper mining companies of the Lake Superior district where the corporate form of organization has entirely superseded firm or individual ownership.

Number of shareholders in Lake copper companies: 1896 to 1902.[1]

YEAR.	Number of shareholders.	Refined copper produced, gross value.	PER CENT OF INCREASE SINCE 1896. Number of shareholders.	Gross value.
1896	6,598	$15,758,935		
1897	7,208	16,530,843	9.2	4.9
1898	8,897	17,829,871	34.8	13.1
1899	11,072	26,098,382	67.8	65.6
1900	18,026	23,691,928	173.2	50.3
1901	20,665	26,038,571	213.2	65.2
1902	22,568	20,100,425	242.0	27.5

[1] The Copper Handbook, Vol. III, pages 573, 574, and 594. The production of 1902 is taken from Census returns. The percentages were computed in the Bureau of the Census.

Production on a small scale.—As may be inferred from the degree of concentration shown above, the day of copper mining on a small scale is past. A survival of old time methods was presented by 3 mines operated by waterpower. The more modern small gas or gasoline engine enabled 12 other mines to conduct operations on a small scale. A summary of these 15 mines, using waterpower or gas exclusively, is presented in the following table:

TABLE 30.—*Summary of mines using only water wheels, or gas or gasoline engines: 1902.*

Number of mines	15
Salaries	$31,043
Wages	$149,902
Contract work	$350
Miscellaneous expenses	$11,611
Cost of supplies and materials	$50,764
Tons of ore produced:	
Total mined	16,528
Sold	5,250
Treated	7,419
Gross value of ore sold or treated	$279,273
Copper contents:	
Pounds	2,634,000
Value	$256,451
Value of by-products:	
Silver	$18,416
Gold	$3,686
Lead	$720
Reduction charges, freight, etc	$106,324
Value of product at mine	$172,949
Expended in development work	$75,216
Average percentage of copper in the ore	10.4
Average value:	
Fine copper, cents per pound	9.7
Gross value per ton	$22.04
Average cost of reduction, per ton	$8.39

The total output of the 15 mines summarized in the preceding table amounted to $172,949 in value, to which should be added the sum of $75,216, representing the value of development work done during the year. The ore was exceptionally rich, yielding 10.4 per cent of fine copper. The average price realized per pound of copper was 9.7 cents, which brought $22.04 per ton of crude ore. The average cost of reduction amounted to

$8.39 per ton, which left $13.65 per ton as value at mine, whereas the gross value of all copper ores mined and treated in the United States averaged only $6.79 per ton. It is probable that it was only the exceptionally high grade of the ore that made mining on so small a scale possible.

The world's production and the world's copper market.—The United States is to-day the chief producer of copper in the world; nearly two-thirds of the world's output in 1902 was furnished by the United States. The following table is a summary of the production of the copper mines of the world:

TABLE 31.—PRODUCTION OF COPPER MINES OF THE WORLD: 1879 TO 1902.[1]

[1] Compiled by Henry R. Merton & Co., Ltd., London; cited in Statistical Compilations of Lead, Copper, Spelter, Tin, Silver, Nickel, Aluminum, and Quicksilver, by the Metallgesellschaft and the Metallurgische Gesellschaft A.-G., 1898, page 10, and 1903, pages 6 and 7.

As shown by the preceding table, North and South America, since 1882, have been the chief source of the world's supply of copper. While the production of South America has declined, North America as a copper producer has, since 1892, overshadowed the rest of the world. Since 1895 the mines of the United States alone have furnished more than one-half of the world's copper.

Among European producers the Iberian peninsula held the first place. Prior to 1882 its output exceeded the production of the United States, and, in 1882, both countries were on the same level, but within the following twenty years the production of Spain and Portugal increased by only about 25 per cent, while the production of the United States in 1902 was more than seven times as large as it was twenty years before.

Mexico, which prior to 1894 was but a small factor in the world's production of copper, has since that year more than trebled its output and gained third place among the copper producing countries.

Next after Mexico was Japan, which since 1890 has doubled its output, and Australia, whose progress has been still more rapid. Germany has shown no appreciable gains since 1896, and has been outranked by Mexico and Australia.

In the table which follows, the refined copper product of smelters and refineries of all countries since 1889, as compiled by the Metallgesellschaft and Metallurgische Gesellschaft A.-G., is compared with the copper contents of the output of all copper mines, as compiled by Henry R. Merton & Co., Limited.

TABLE 32.—*Copper output of mines and smelters of all countries: 1889 to 1902.*[1]

YEAR.	MINES.	SMELTERS.	
	Metric tons.	Metric tons.	Per cent of mine output.
Total	5,389,009	5,404,885	100.3
1889	265,384	267,182	100.7
1890	273,765	282,251	103.1
1891	283,861	291,225	102.6
1892	315,439	317,137	100 5
1893	308,387	304,700	98.8
1894	329,698	328,000	99.5
1895	339,919	351,500	103.4
1896	379,337	393,200	103.7
1897	406,126	418,900	103.1
1898	436,500	433,300	99.3
1899	479,800	480,000	100.0
1900	492,556	487,200	98.9
1901	527,089	517,550	98.2
1902[2]	551,148	532,700	96.7

[1] Cited in report by the Metallgesellschaft and Metallurgische Gesellschaft A.-G., 1903.
[2] Figures for United States exceed United States Census figures by 6,149,608 pounds. As the difference is less than 1 per cent, the estimate of Henry R. Merton & Co., Ltd., is retained for the sake of comparison.

The variations between the output of mines and smelters have been confined within narrow limits, viz, between 3.7 per cent above and 3.3 per cent below the mine output. This close agreement is due to the fact that copper is mostly mined and smelted by the same producers; either quantity may therefore be used for comparisons.

The following table shows the growth of the world's production of copper during the past century:

TABLE 33.—*Growth of the world's copper production in the nineteenth century.*[1]

[Long tons.]

DECADE.	World's production of each decade.	Increase of production over previous decades.	Average annual production for each decade.	Increase of average annual production.
1801 to 1810	91,000		9,100	
1811 to 1820	96,000	5,000	9,600	500
1821 to 1830	135,000	39,000	13,500	3,900
1831 to 1840	218,400	83,400	21,840	8,340
1841 to 1850	291,000	72,600	29,100	7,260
1851 to 1860	506,999	215,999	50,699	21,599
1861 to 1870	900,000	393,001	90,000	39,300
1871 to 1880	1,189,000	289,000	118,900	28,900
1881 to 1890	2,373,398	1,084,398	237,339	108,439
1891 to 1900	3,708,901	1,335,503	370,890	133,550

[1] The Copper Handbook, Vol. III, page 565.

A study of the table shows that during the first two decades of the past century the production of copper remained practically stationary. From 1820 to 1880 the average yearly production more than doubled once in every twenty years. Within the last two decades of the century the annual average production more than trebled, increasing from 118,900 tons during the years from 1871 to 1880 to 370,890 tons from 1891 to 1900. The annual average output from 1881 to 1890 exceeded the average for the preceding decade by 118,439 tons, i. e., by 99.6 per cent, and the annual average for the years from 1891 to 1900 showed an increase over the preceding decade amounting to 133,551 tons, or 56.3 per cent. Though the increase in production during the last decade was absolutely greater than during the preceding period, yet owing to the enlarged volume of production the relative increase appears smaller.

The extraordinary progress of copper mining within the last two decades was stimulated by the rapid extension of the uses of electricity to all branches of industry. The United States has been the chief factor in this progress. The production of the United States increased from 1879 to 1902 more than twelvefold. The share of the United States in the progress of copper mining is shown in the following comparative summary by quadrennial periods:

TABLE 34.—OUTPUT OF COPPER MINES OF THE UNITED STATES AND OTHER COUNTRIES, BY QUADRENNIAL PERIODS: 1879 TO 1902.[1]

[Long tons.]

PERIOD.	TOTAL PRODUCTION.				INCREASE OVER PRECEDING PERIOD.			
	All countries.	United States.	Other countries.	Per cent United States.	All countries.	United States.	Other countries.	Per cent United States.

[1] Henry R. Merton & Company's figures, cited in the report by the Metallgesellschaft and Metallurgische Gesellschaft A.-G., October, 1903.
[2] Figures for United States exceed United States Census figures by 6,149,608 pounds. As this is less than 1 per cent, the estimate of Henry R. Merton & Co. Ltd., is retained for sake of comparison.

Up to the period from 1895 to 1898 the United States was rapidly gaining over all other countries. From 1887 to 1894 practically all the increase in the world's production of copper came from the United States. During the years from 1895 to 1898 the United States outranked all other countries. During the last period, closed by the census year 1902, the production of the United States maintained its rate of growth, but mining in other countries took on a new life under the stimulus of high prices, as will be shown below, and the increase in their output nearly reached that of the United States.

In Table 35 the world's production and consumption of copper are shown since the year 1895, when the United States surpassed the total production of all other countries. All countries are arranged in two classes: (1) Those whose domestic consumption of refined copper exceeded the output of their own mines, and (2) those whose mines produced more than was consumed at home. For the sake of brevity, the former are designated as "importing countries" and the latter as "exporting countries."

It must be understood, however, that some of the countries designated here as "importing" also exported considerable quantities of copper, while those designated as "exporting" may have imported copper ore, matte, etc., to be later reexported as refined copper.

In calculating the domestic consumption for each country its imports are added to its production, and its exports are deducted from the total; the increase or decrease of the stocks of copper from year to year is also taken into account wherever ascertainable. The estimate of domestic consumption which is arrived at in this manner represents the supply of copper available for domestic consumption, but is not necessarily identical with the quantity actually consumed in manufactures for which copper serves as material.

In Table 35 the column headed "product of mines" represents only the production of copper from domestic ores, as reported by Henry R. Merton & Co., Ltd.; the column "consumption" represents the supply available from all sources for domestic consumption, as computed by the Metallgesellschaft and Metallurgische Gesellschaft A.-G.; the "net demand for imported copper" in the list of importing countries and the "net supply available for export" in the list of exporting countries represents, in each case, the difference between the totals of the two columns just mentioned. The table thus shows, on the one hand, the share contributed by each copper mining country to the world's supply of copper, and on the other hand the demand for unmanufactured copper directly exercised by the manufacturing industries of each country.

[1] Includes Argentina, Bolivia, and Peru.

The recapitulation which follows shows the share of the world's output consumed at home and exported; the domestic consumption is obtained by adding the production of importing countries to the domestic consumption of exporting countries.

TABLE 36.—*World's production, domestic consumption, and supply available for export, with per cent of total production: 1895 to 1902.*

1902	542,470	253,138	289,332	46.7	53.3

Tables 35 and 36 bring out the fact that copper is preeminently an article of international trade. More than one-half of the copper mined was exported for consumption to other countries. With the exception of the United States, the principal producers of copper had practically no market for it at home. The United States, though holding the first place among the consumers of copper, was also largely dependent upon the foreign market for the sale of the product of its mines.

There is a difference amounting from a fraction of 1 per cent to over 10 per cent between the total net supply available for export and the total net demand for imported copper. The variance is due in part to the well-known disagreement between export and import statistics and partly to the fact that the resmelting of old copper enters into the calculation of the consumption for some countries.

On the whole, the copper mines of the United States have since 1895 supplied over one-third of the demand for imported copper, as shown in the following table:

TABLE 37.—*Consumption of copper in importing countries and exports of domestic copper from the United States: 1895 to 1902.*

[Long tons.]

YEAR.	Importing countries' net demand for imported copper.	Available for export in the United States.	Supplied by other countries.
Total	2,060,638	708,473	1,352,165
1895–1898	996,556	389,440	607,116
1899–1902	1,064,082	319,033	745,049
1895	205,835	55,867	149,968
1896	253,761	109,469	144,292
1897	268,747	111,766	156,981
1898	268,213	112,338	155,875
1899	240,845	76,355	164,490
1900	285,038	117,360	167,678
1901	244,639	30,677	213,962
1902	293,560	94,641	198,919

The principal consumers of copper besides the United States were Great Britain, Germany, and France. The same countries were also the principal importers of

copper, while the United States, Spain, and Portugal were the principal exporters of domestic copper. Next after Spain and Portugal as exporters of domestic copper followed, in consecutive order, Mexico, Chile, Japan, Australia, and Canada.

Europe being the principal market for copper, a comparative table is next presented showing in parallel columns the gross exports to Europe from other continents, the net supply of domestic copper available for export, and the excess of the one over the other.

The preceding table clearly shows the place of each producing country in the world's copper trade. Beginning with the year 1896, the United States showed a growing excess of exports to Europe over its domestic supply, whereas in all other copper producing countries the supply available for export exceeded the direct exports to Europe. The excess of the exports from the United States in 1901 and 1902 was very near the surplus of all other countries, after deducting their direct exports to Europe. These figures demonstrate that the United States has within late years gained control of the export trade of non-European copper producing countries.

A closer study of the statistics shows that the direct exports to Europe from Canada and Mexico have fallen off slightly, while the supply of copper available in these countries for export has more than trebled since 1895. All this copper found its way to the United States, to be reexported to Europe. The direct exports to Europe from Canada and Mexico are but a minor portion of their total copper exports. The United States has also a fair share of the copper trade of Japan, Australia, and Chile, though these countries for the most part maintain direct relations with Europe.

The share of the United States in each of the principal European copper markets, namely, Great Britain, Germany, and France, is shown in the following table. The imports reported by these countries from the United States represent actual exports from this country, both of domestic and foreign copper.

Germany was the largest European consumer of American copper. The German copper market depended upon the United States for more than one-half of its supply, the balance being furnished by the German mines and by imports from other countries. The second place among the consumers of American copper was held by Great Britain; the position of American copper in the English market was important, yet far from dominant. The French market has, since 1896, developed a large demand for American copper; in 1902 two-thirds of the copper consumed in France was imported from the United States.

International organization among producers.—The degree of concentration which has been noted in the United States was also characteristic of the copper mining industry in other countries.

In Spain the two largest mines, the Rio Tinto and the Tharsis, were operated by English corporations, the former being controlled by the Rothschild interests.[1] The Rio Tinto produced in 1901, 79,279,520 pounds of fine copper, and the Tharsis 16,636,480 pounds. They furnished four-fifths of the production of Spain.

In Mexico the two largest mining companies were the Greene Consolidated Copper Company, an American corporation, and the Compagnie du Boleo, supposed to be controlled by the French house of the Rothschilds.[2] The former reported, for the year ending August 1, 1902, a product of 27,854,497 pounds of fine copper in matte and bullion,[3] and the latter produced in 1901, 24,153,197 pounds.[4] The combined production of these two mines represented two-thirds of the total output of Mexico.

In Germany the Mansfeld mines produced in 1901 42,067,200 pounds of copper, which was practically all the copper produced in Germany.

The concentration of the copper mining industry under the control of a limited number of companies facilitated organization among them. The first attempt at organization was the Secretan syndicate, which was formed in Paris in the fall of 1887, with the object of improving the price of copper. The syndicate was organized with a capital stock of 100,000,000 francs, divided into shares of 1,000,000 francs each. In October, 1887, fine copper was quoted in London at from £39 to £40 per ton. The syndicate made contracts with mining companies in all parts of the world for their entire supply at prices ranging from £68 to £70 per ton.

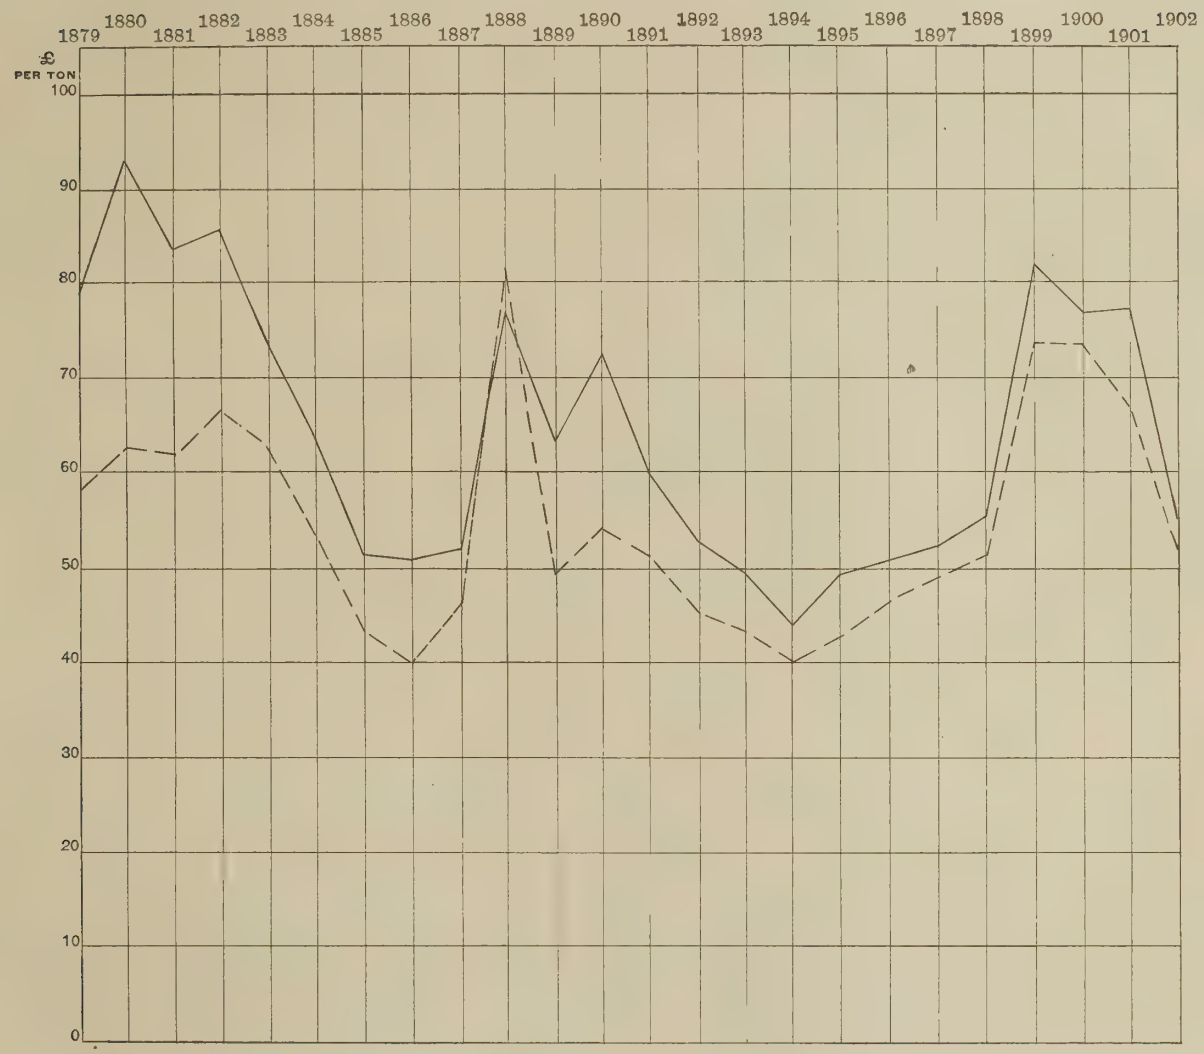
DIAGRAM I.—AVERAGE PRICES OF COPPER, NEW YORK AND LONDON: 1879 TO 1902.



———Price at New York — — — —Price at London

30223—04——32

The price of copper immediately took an upward course and was soon driven as high as £100 per ton. High prices stimulated the extension of mining, and the output was greatly increased. In order to sustain the price the syndicate was compelled to buy all copper that was offered to it. On the other hand, consumers reduced their stock to the lowest limit, preferring to buy from day to day. As a result, the visible stock of copper rapidly increased, rising from 42,301 tons on January 1, 1888, to 104,105 tons a year later. Though it was financed by one of the leading French banks, La Banque de Paris et de Pays Bas, and had the support of the Bank of France, the scheme finally collapsed, ending in the bankruptcy of the syndicate.[1]

In 1892 an organization was created, known as the European Producers' Committee. It represented the principal mines of Spain and Portugal, Germany, the Cape Colony, Mexico, and Australia, and was managed by European boards of directors. The mines have reported their output each month to a secretary in London since July, 1892.[2] As previously stated, simultaneously with the European organization, the American Producers' Association was organized, and both organizations maintained friendly relations and exchanged monthly reports with each other. The share of the world's output which was controlled by these two organizations is shown in the following table:

TABLE 40.—*World's production and output of American and foreign reporting mines: 1893 to 1902.*

[Long tons.]

YEAR.	World's production.[1]	PRODUCTION OF REPORTING MINES.			
		American.[2]	Foreign.[2]	Total.	
				Quantity.	Per cent of world's product.
1893	303,530	142,490	81,785	224,275	73.9
1894	324,505	159,623	88,531	248,154	76.5

In 1903 large producing interests withdrew from the American Association, declining to furnish statistics in the future, so that the monthly compilations have ceased.[3] Considering that the United States supplies two-thirds of the copper product of the world, the termination of the understanding between American producers means that the international organization among copper producers, which was represented by the two associations, has practically come to an end.

Prices.—The price of copper governing in the United States is the New York price for Lake copper, the price of electrolytic copper, being usually from one-eight to one-fourth of a cent lower; the price ruling in the international market is the London price for standard copper. Table 41 is a comparative table showing the average annual prices of copper in New York and London since 1879.

TABLE 41.—*Average prices of copper, London and New York: 1879 to 1902.*[1]

YEAR.	Standard copper at London, price per long ton.	LAKE COPPER AT NEW YORK.	
		Cents per pound.	English equivalent (£ per long ton).

[1] "Comparative Statistics of Lead, Copper, etc.," compiled by the Metallgesellschaft and Metallurgische Gesellschaft A.-G., October, 1903, page 10.

The movement of prices is illustrated by Diagram I. The solid line representing the New York price runs above the broken line representing the London price, with the single exception of the year 1888, when the London price, by a sudden bound, rose to heights never witnessed either before or since within the last two decades. Although the New York price promptly responded, yet for once it stopped below the London price. The reason for this extraordinary rise was the attempted corner of the London market by the Secretan syndicate. The failure of the scheme drove the London price down; the New York price also receded, yet not quite as low, and the former relative position was restored.

The opening of copper mines in Montana and Arizona resulted in a downward tendency of prices from 1882 to 1886, which is shown by the movement of both lines in the diagram. A slight improvement marked the year 1890, after which a downward movement set in

DIAGRAM II.—PRODUCTION, CONSUMPTION, AND EXPORTS OF COPPER IN THE UNITED STATES: 1895 TO 1902.

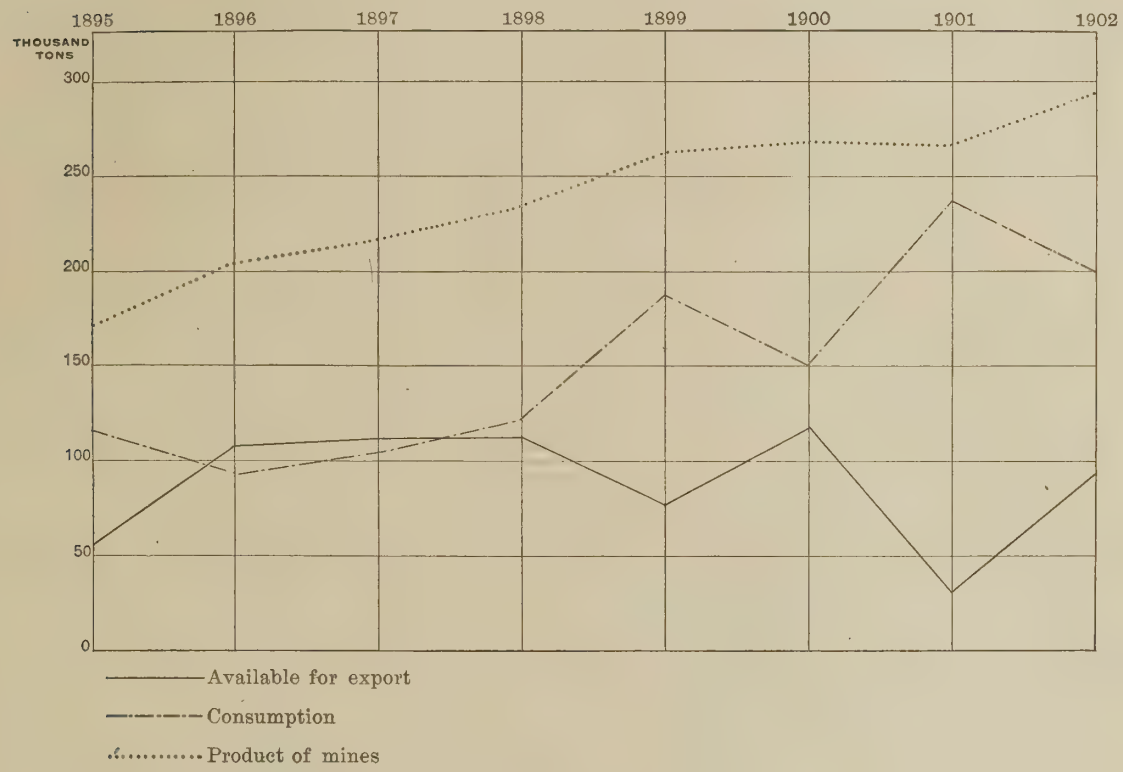

DIAGRAM II A.—AVERAGE NEW YORK PRICES OF COPPER: 1895 TO 1902.

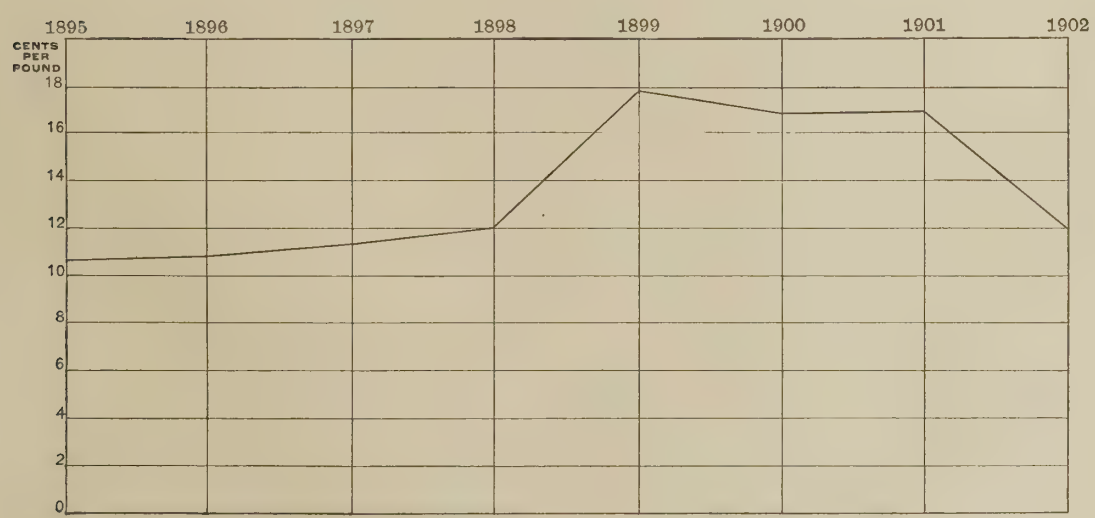

again, which touched its lowest point in 1894. The lines then take again an upward course.

The diagram also makes possible a study of the effect of organization among producers upon the movement of prices. Since 1892 the copper producers have kept informed from month to month concerning the output of the principal copper mines in all parts of the world. The output of the mines outside of the European and American associations did not exceed one-fourth of the world's production of copper. Thus the principal mines have been enabled to adjust their production with regard to the general state of the copper supply. The diagram shows that this knowledge of the demand and supply has not had the effect of steadying the prices; the range of fluctuations in New York and London since 1892 has been as wide as it was prior to that year. The difference between the New York and the London price shown by the distance between the solid and the broken lines has somewhat narrowed and, through all the vicissitudes of the market, has been less subject to fluctuation than before 1892.

In 1899 the Amalgamated Copper Company was organized. According to an official statement issued by the company, it adopted from the beginning the "policy of maintaining a firm price." Its selling agents were therefore "instructed not to attempt to force upon the market more than was actually needed for consumption, but to maintain a firm price."[1] The price was raised from 12 cents to 17 cents in 1899 and was maintained, with a slight reduction, until December, 1901, when the company was forced to reduce the price to the former level of 12 cents. The reason given for this reduction was the failure of other copper producing companies to take the same view of the situation and to maintain a firm price by restricting their output. The effect of this policy upon the copper trade can be studied from the preceding tables and the diagrams illustrating the same.

Diagrams II and II_A show the production of copper in the United States, the supply held for domestic consumption, the domestic supply available for export, and the average New York prices of copper from 1895 to 1902. The upward movement of the solid line in Diagram II_A, representing the New York price, is followed by a similar movement of the dotted line in Diagram II representing the copper output of the mines in the United States. The solid line in Diagram II representing the net domestic supply available for export moves in the opposite direction; the rise of prices in 1899 is shown to have been accompanied by a decrease of exports; in 1900 a slight reduction in the price was attended by an increase of exports; in 1901 the price was maintained, but the exports sank to the lowest point; in 1902 the slump in the price was followed by an increase of the exports. The solid line in Diagram II_A representing prices and the dash-and-dot line representing in Diagram II the amount of the domestic product held at home and available for domestic consumption run almost parallel.

The movements of the solid line in Diagram II_A and of the dotted line in Diagram II indicate that the high prices of 1899 to 1901 stimulated production. In order to maintain a firm price it was necessary to reduce exports, which resulted in an increase of the supply available for domestic consumption.

The relation between the available supply and the actual demand for domestic consumption in 1900, 1901, and 1902 is shown in the data published by the United States Geological Survey. The available supply is computed by adding the production of domestic copper and imports of copper in ore, matte, bars, etc., entered for consumption, and by deducting from the sum the exports of copper. The demand, or estimated consumption, is obtained by deducting the increase in producers' stocks from the available supply, or by adding to it the decrease in producers' stocks. The following statement shows the relation of supply and demand to prices:[2]

Supply and demand and prices in the United States: 1900 to 1902.

YEAR.	Supply (pounds).	Demand (pounds).	Excess of supply over demand (pounds).	Excess of demand over supply (pounds).	PRICE OF LAKE COPPER IN NEW YORK (CENTS PER POUND).	
					Highest.	Lowest.
1900	362,891,121	356,891,121	6,000,000	.....	17¼	16
1901	517,761,014	382,761,014	135,000,000	.....	17	12⅞
1902	425,339,486	551,688,131	.....	126,348,645	13¼	10⅞

In 1900 the copper producers managed to keep the supply close to the limits of demand; the price was maintained between 16 and 17¼ cents per pound. In 1901 the domestic demand remained almost stationary, but the supply increased enormously, which was due to a reduction in the foreign exports. In the face of this increased supply the price was for fully eleven months held at the same level as during the year before, and only in December, 1901, was it reduced to 12⅞ cents. Except for a brief slump to 10⅞ cents in January, 1902, and a rise to 13¼ in February, the price during the year fluctuated between 11½ and 12¾ cents, and at these prices nearly all of the surplus was absorbed in the domestic market; the demand in 1902 exceeded by 44 per cent that of the previous year.

The effect of high prices upon the American trade with Europe is shown in Diagram III. The solid line representing the net demand for imported copper and the dotted line representing the share supplied by the United States run almost parallel. An increase of the demand in Europe, as here represented, increases imports from the United States; a slackening of the demand reduces imports from the United States. At

DIAGRAM IV.—CONSUMPTION OF IMPORTED COPPER IN GREAT BRITAIN, IMPORTS FROM THE UNITED STATES AND OTHER COUNTRIES: 1895 TO 1902.

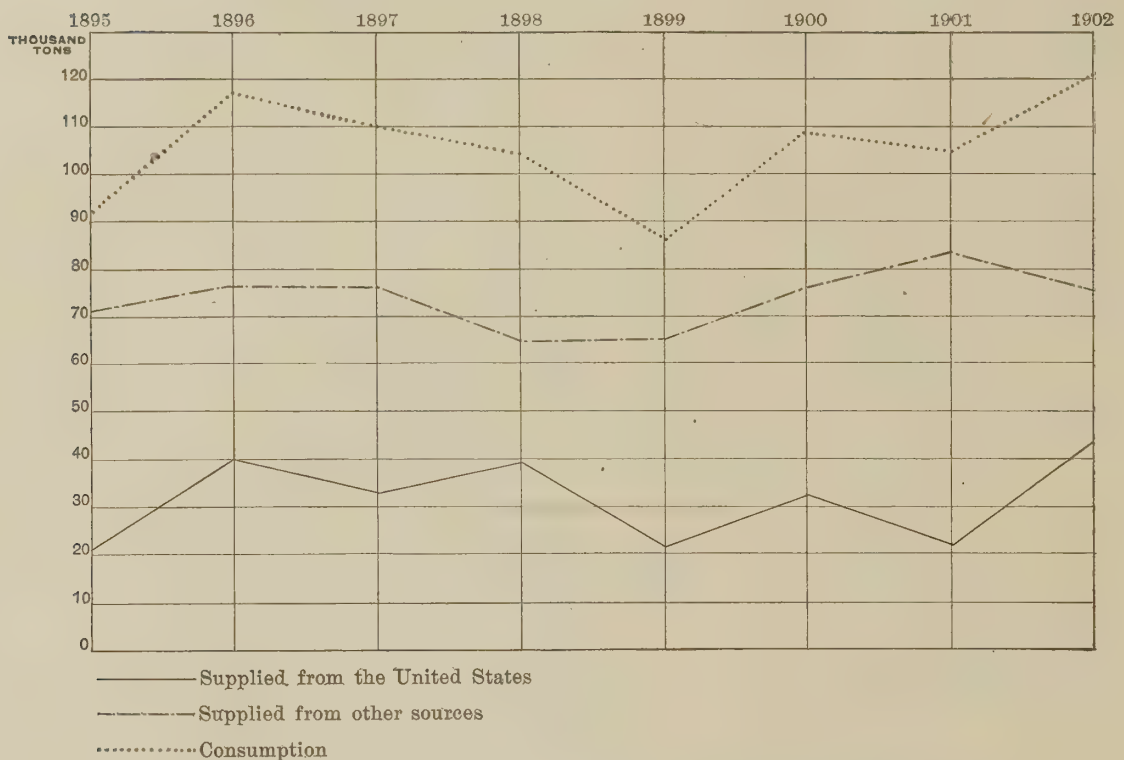

DIAGRAM IV A.—AVERAGE LONDON PRICES OF COPPER: 1895 TO 1902.

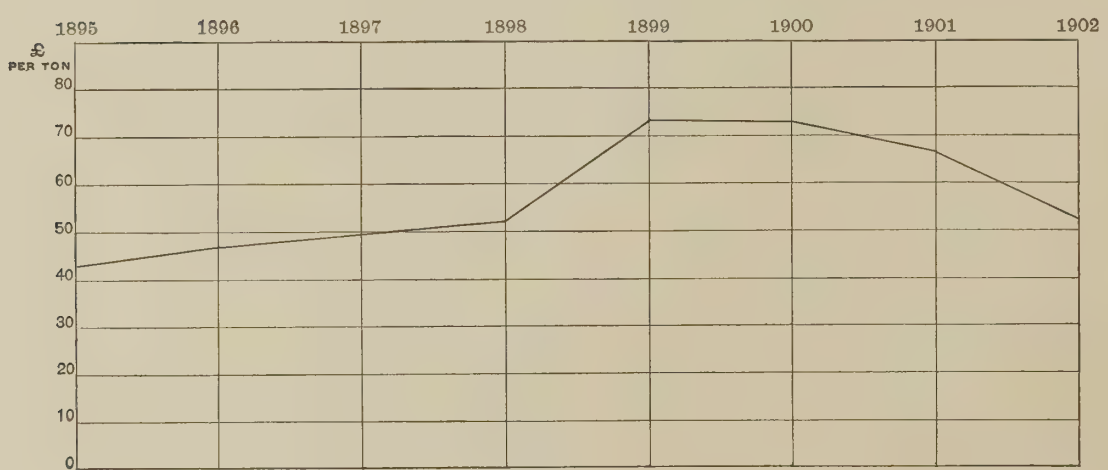

DIAGRAM V.—CONSUMPTION OF COPPER IN FRANCE:
1895 TO 1902.

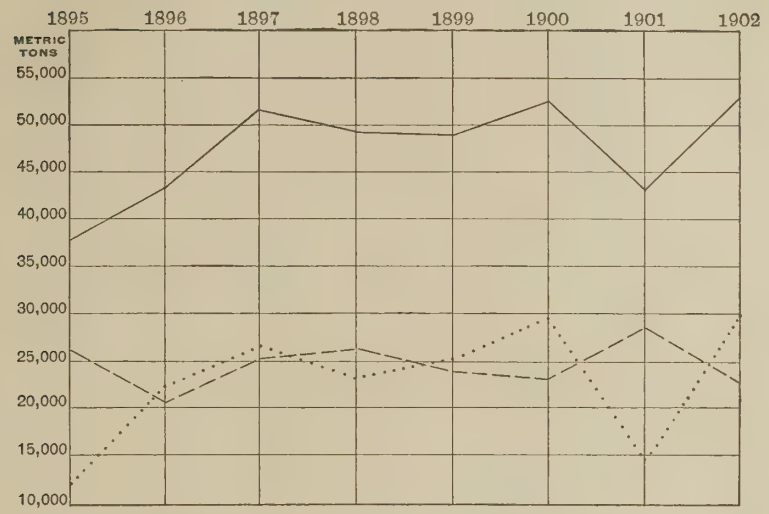

DIAGRAM VI.—CONSUMPTION OF COPPER IN GERMANY:
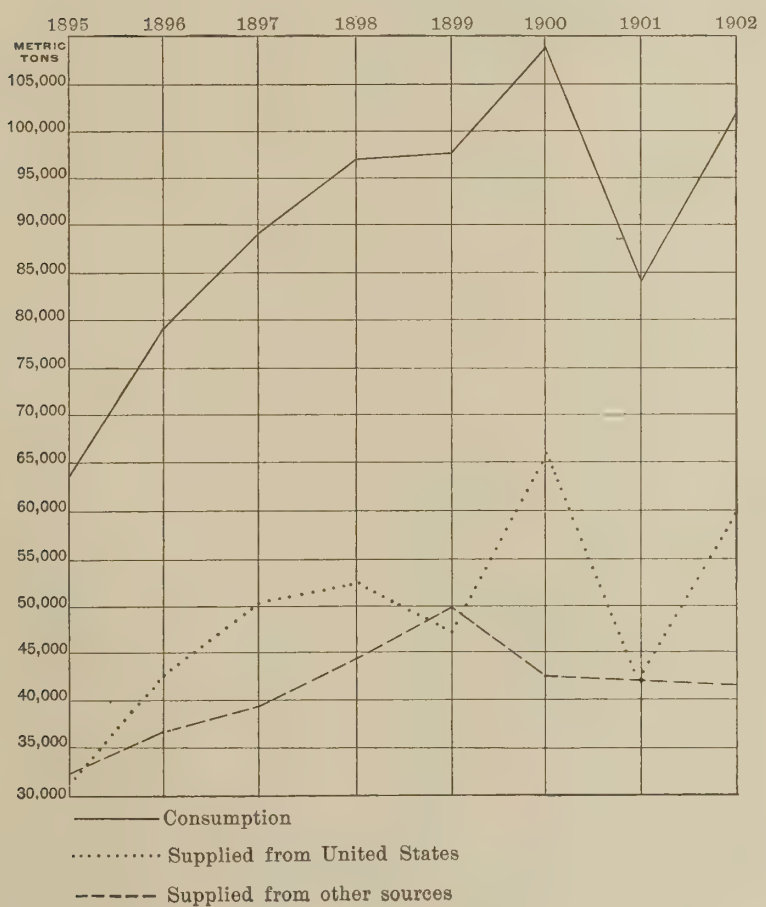
1895 TO 1902.



the same time, with reduced exports from the United States, the line of dashes representing the imports from other countries is slowly rising; in 1901, notwithstanding the fall in the European demand, the line suddenly goes up, while imports from the United States show a heavy decline. The rise of the demand and a parallel rise of the imports from America in 1902 are accompanied by a decline in the imports from other sources.

A comparison of the totals for the quadrennial periods 1895 to 1898 and 1899 to 1902 (see Table 37) shows that while the European demand rose from 996,556 to 1,064,082 long tons, the imports from the United States fell from 389,440 to 319,033 tons.

The effect of the latest price movement upon the American export trade was not alike in the principal European markets.

Diagrams IV and IV_A illustrate the correlation between the London price, the consumption in Great Britain, and the imports from the United States and other countries. The results appear to be the same as shown for Europe as a whole. In the French market the decline of American imports, as shown in Diagram V, created somewhat of an increase in the imports from other countries, not, however, corresponding to the shortage of the former. Diagram VI shows for Germany a parallel movement between the consumption of that country and the imports from the United States; yet the decline of American imports in 1901 did not increase the imports from other countries.

While the effect of high prices from 1899 to 1901 upon the export trade may appear unfavorable, yet it was declared by the Amalgamated Copper Company, in its official statement, that "the portion of the copper which has been sold has realized a larger profit than would have been realized had all the copper which had been produced been sold at a much lower price." This view is borne out by the following comparison of the production, prices, and dividends for the years 1895 to 1902:

Production, prices, and dividends: 1895 to 1902.

YEAR.	Production of copper (pounds).	Average price per pound (cents).	DIVIDENDS.	
			Amount.	Average per pound (cents).
1895	380,614,080	10.73	$4,200,000	1.10
1896	460,060,160	10.98	5,575,000	1.21
1897	494,079,040	11.36	8,222,000	1.66
1898	526,512,000	12.05	12,647,000	2.40
1899	568,668,800	17.76	28,042,000	4.93

GOLD AND SILVER

GOLD AND SILVER.

By Isaac A. Hourwich, Ph. D.

Gold and silver mines as treated in this chapter embrace (1) gold washings, commonly known as placers; (2) deep mines, which yield gold and silver bearing ore; and (3) ore dressing and reduction works, commonly known as mills, and operated either in connection with mines or independently. Smelters were classified at the Twelfth Census as manufacturing establishments, and were therefore excluded from the census of mines and quarries.

The precious metals being frequently associated in the ore with base metals, a proper classification of mines by the character of metals produced is attended with certain difficulties and must perforce appear artificial. Thus, from a mineralogical or metallurgical point of view, an ore assaying 50 pounds of copper to the short ton and only 1 ounce of gold is a copper ore, whereas from a commercial standpoint it is a gold ore, since the value of the 1 ounce of gold is about three times the value of the copper contained in the ore. The criterion must be determined by the object of the classification. The object of an industrial census being primarily the study of economic conditions, the classification of industries must be based upon an economic test.

The product of a mine is accordingly defined here as a gold and silver ore whenever the precious metals constitute the principal elements of its commercial value. The statistics relative to the mining of copper ores carrying small values in gold and silver are presented, together with those for other copper ores. Argentiferous iron ores, valued chiefly as fluxing material, though carrying small quantities of silver, are classed with iron ores.

This rule, like any other, is not without exceptions. The value of argentiferous lead ores follows the fluctuations in the market prices of silver and lead. The price of silver in 1902 was the lowest in many years. As a result, some mines, whose product at the prices ruling in 1901 was regarded as silver ore, realized in 1902 less for the silver than for the lead contents of their ore. Many more mines, which at the previous censuses were classed as silver mines, would now have to be considered lead mines, if judged by the relative values of the silver and lead contents of their ores. Such a classification would obviously be purely accidental and would destroy the value of all comparisons with the results of previous censuses. It was, therefore, deemed necessary to include all argentiferous lead mines among gold and silver mines.

There was, furthermore, a very numerous class of mines whose operations in 1902 were confined to development work. Any classification of such mines by the character of the ore in sight in advance of actual production is of necessity arbitrary. Though the work may at present be pursued with the prospect of finding gold and silver in paying quantities, many of these mines, in the light of past experience, will develop into copper, iron, or zinc mines. Yet the commercial nature of the investment impresses all such ventures with the character of gold and silver mines.

Census statistics of the gold and silver industry from 1860 to 1902 are summarized in the following table:

TABLE 1.—COMPARATIVE SUMMARY: 1860 TO 1902.

[1] All statistics, except for product, for deep mines only.
[2] Not reported.
[3] Establishments.
[4] Includes 2,937 salaried employees whose salaries are included in amount paid wage-earners and are not separable therefrom.
[5] Includes an estimated production of $1,138,181 for a number of small mines for which no reports were received directly from operators.
[6] The value of the copper and lead by-product for Utah, Colorado, and Montana, $4,689,178, is added to the value of the precious metals. The product included 31,797,474 ounces of silver, which were reported at coining value. For the purpose of comparison the value has been reduced to commercial value, at the rate of $1.134 per ounce fine, which was the average for the year 1879 and 1880. The total value reported at the Tenth Census was $79,179,798.

Few reliable comparisons can be based upon the figures summarized in Table 1, as the method of collecting and presenting the data varied from census to census. The statistics for 1889 include those for mines at which only development work was done. This is probably true of the previous Census reports. The totals for 1902 were therefore summarized to show also the statistics of mines reporting development work only.

Development work.—In Table 1 is shown the extent of development work done in mines from which no production was reported. This kind of work was generally prosecuted to some extent in producing mines as well, but was always reported as a part of the ordinary mining expenses. In many cases the account was kept separately; where it was not, no separate report could be made, for the operators were unable to estimate the cost with any degree of accuracy. The total amount expended by regular producers, as far as reported, was $4,683,929. There were, moreover, a number of mines the expenditures for which largely exceeded the receipts. In some instances this may have been due to a poor grade of ore; in others to unfavorable conditions which made mining unprofitable. In most cases, however, an examination of the mine reports disclosed no difference in the grade of ore or the charges for treatment and freight as compared with other producing mines of the same district; the excess of expenditures over returns was therefore presumably due to outlays for development. All such reports were classified separately. This classification was not extended, however, to mines combined with mills, for in such cases heavy expenditures might have been incurred for mill equipment and construction work other than development. A summary of such mines, distinguished as "developing and producing," is presented in the following table, in parallel columns with data relating to regular producers, designated as "productive:"

TABLE 2.—*Comparative summary of productive and of developing and producing mines without mill connection in the United States: 1902.*

	DEEP.		PLACER.	
	Productive.	Developing and producing.	Productive.	Developing and producing.

Value of product at mine	$20,507,436	$2,668,636	$3,958,728	$230,817

Number of mines and operators.—These terms, whose meaning is perfectly plain in ordinary language, require a further definition when applied in a statistical sense to gold and silver mining.

There are few mines which represent one original location; most of the mining properties represent "groups" of mines, which were at some time past operated as independent undertakings, but have since been united, by purchase, lease, or otherwise, under one management. The identity of some of these mines may still be preserved; in most cases, however, their accounts are not segregated, or are only imperfectly segregated, on the books of the present owners. Thus

some operators will make a separate report for each mine, while others will make one report for the group, though the difference between the properties may be in the system of bookkeeping rather than in mining conditions.

Where a mine was operated by a lessee a report was required from him. But in some mining districts it is customary to apportion the mine, in small allotments or "blocks," among a number of miners working on a royalty and designated as "lessees." The shifting character of this class of "lessees" precluded a complete canvass of their operations; in all such cases the owner of the mining property was required to make one report covering all his lessees.

In placer mining there are numerous prospectors and gold seekers moving from place to place who can not be reached by a census of mines. These miners are not included in the number of operators, but their production was ascertained from other reliable sources and is included.

A number of mines changed hands in the course of the year, and separate reports were received from each of the parties by whom the mine was successively operated. While the location and equipment of the mine remained the same, yet the character of ownership, capitalization, method of treatment of the ore, etc., in some cases had undergone a change; a combination of heterogeneous reports, made by different operators, into one, for the mines, was impracticable. Mills operated in connection with mines were by some operators reported separately and by others were included in the mine report.

In order to meet all these varying conditions it was deemed advisable to accept every individual report as a unit of enumeration, except that reduction works when connected with mines were in all cases counted as a part of the mine equipment. The number of mines and the number of operators as given in the tables are, therefore, identical. The total number of active mines, as here defined, was 2,992.

There were, furthermore, 3,252 mines which were operated in 1902 but reported no production, the work being confined to the development of the mines. This does not include mining prospects upon which "assessment work" was done, i. e., the quantity of labor required by law as a condition for holding title to the mining claim. The scope of the census of mines and quarries did not comprise a canvass of mining prospects, but a number of mining properties locally reported as active or in the development stage proved upon inquiry to be mere prospects. The number of claims which were thus reported and the number of their owners are shown in the following table, by states and territories, arranged according to the number of claims reported:

TABLE 3.—*Mining prospects upon which assessment work was done, by states and territories: 1902.*

STATE OR TERRITORY.	Number of owners.	Number of claims.
United States	5,135	5,511
California	1,219	1,322
Washington	944	995
Colorado	618	633
Oregon	422	502
Idaho	460	476
Nevada	419	439
New Mexico	403	403
Arizona	384	389
Utah	194	213
South Dakota	31	98
Wyoming	20	20
Montana	17	17
Arkansas	2	2
Alabama	1	1
North Carolina	1	1

As shown by Table 3, the attention of the prospectors was turned mainly to California, Washington, and Colorado, over one-half of the claims being located in those 3 states. The lowest rank among the Western states was held by Montana, which reported only 17 prospectors. Prospecting in the Southern states was exceptional. The total number of claims reported exceeded but little the number of owners. There were in all 43 owners reporting more than one claim each, and the total number of claims held by them was 419; the highest number of claims held by one owner was 32, and was reported from Oregon. The following table shows the distribution of owners by the number of claims held:

TABLE 4.—*Distribution of mining prospectors by number of claims held: 1902.*

NUMBER OF CLAIMS HELD BY EACH PROSPECTOR.	Number of owners.	Number of claims.

11	1	11
13	1	13
14	1	14
16	2	32
20	1	20
28	1	28
30	2	60
32	1	32

The total number of mines reported as idle was 3,957. This number embraces only mines which had been previously reputed as active, and the owners of which were therefore either communicated with by mail or visited by special agents. There were doubtless many more mines which had at some time been operated, but were idle in 1902.

Character of ownership.—The majority of gold and

silver mining enterprises in 1902 did not have an incorporated form of organization. A distinction is to be noted in this respect between deep mines and those in the development stage on the one hand and placers on the other hand; while about one-half of the former were operated by incorporated companies, the owners of only about one-sixth of the latter were incorporated. Another noteworthy fact is that the majority of incorporated companies were engaged exclusively in development work, whereas the majority of firms and individuals operated producing mines. It would seem, therefore, that the corporate form of ownership is more favorable to the development of modern mines. The following table presents the classification of all mines by character of ownership:

TABLE 5.—*All mines, classified by character of ownership: 1902.*

	Total.	Incorporated company.	Firm.	Individual.	Other form.
All mines	6,244	2,774	1,772	1,641	57
Producing mines:					
Total	2,992	1,079	923	958	32
Deep	2,017	923	575	501	18
Placer	975	156	348	457	14
Development work	3,252	1,695	849	683	25

The mines classed as "other form" included cooperative associations, mines held in joint ownership and by estates, etc.

The corporate form of ownership was especially prevalent among producing mines in Arizona, Colorado, and Utah; the owners of more than one-half of all mines in the first two and of four-fifths of those in the last-named state being incorporated companies. Among mines reporting development work only, the corporate form predominated in Arizona, Nevada, Oregon, South Dakota, Utah, Washington, and Wyoming.

The share contributed by each type of organization to the production is shown in Table 6.

TABLE 6.—*Producing mines, classified by character of ownership and value of product: 1902.*

CHARACTER OF OWNERSH..	Number of operators.	VALUE OF PRODUCT AT MINES. Total.	Per cent.	Average per mine.
All mines	2,992	$82,482,052	100.0	[1] $27,021
Incorporated company	1,079	68,327,754	82.8	63,325
Firm	923	8,398,221	10.2	9,099
Individual	958	3,890,304	4.7	4,061
Other form	32	231,938	0.3	7,248
Not classified	.....	1,633,835	2.0	.....
Deep mines	2,017	77,154,326	100.0	[1] 38,006
Incorporated company	924	65,831,994	85.3	71,247
Firm	576	7,577,430	9.8	13,155

Placer mines	975	5,327,726	100.0	[1] 4,297
Incorporated company	155	2,495,760	46.9	16,102
Firm	347	820,791	15.4	2,365
Individual	459	781,769	14.7	1,703
Other form	14	91,225	1.7	6,516
Not classified	.....	1,138,181	21.3	.....

[1] The "not classified" product was excluded in obtaining this average.

The preceding table shows that the corporate form of ownership, though adopted by only a little over one-third of all active operators, figured in more than four-fifths of the total output of the mines and showed the largest output per mine. Both firms and individuals belonged to the small type of producers. Other forms of organization represented but three-tenths of 1 per cent of the total output. The corporate form of ownership played a more important part in deep than in placer mining, the ownership of about one-half of all deep mines, contributing over five-sixths of the product, being that of incorporated companies, whereas the number of incorporated owners of placer mines was less than one-sixth of all placer mines, and their product was but about one-half of the total for all mines.

The following table is a summary for mines owned by incorporated and by unincorporated operators:

TABLE 7.—SUMMARY FOR ALL MINES, BY CHARACTER OF OWNERSHIP: 1902.

	ALL MINES. Total.	Incorporated.	Unincorporated.	DEEP MINES. Total.	Incorporated.	Unincorporated.	PLACER MINES. Total.	Incorporated.	Unincorporated.
Number of operators	2,992	1,079	1,913	2,017	924	1,093	975	155	820

Total gross value	$97,459,235	$84,086,329	$13,372,906	$93,254,240	$81,581,333	$11,672,907	$4,204,995	$2,504,996	$1,699,999
Average value per ton	.....	.....	.....	$10	$10	$11	.....	.....	.....
Value of product at mine[1]	$80,848,217	$68,327,754	$12,520,463	$76,658,672	$65,831,994	$10,826,678	$4,189,545	$2,495,760	$1,693,785
Average per mine	$27,021	$63,325	$6,545	$38,006	$71,247	$9,905	$4,297	$16,102	$2,066

[1] In addition to this, $1,633,835 represents the product of mines for which the number of operators and character of ownership was not reported, $495,654 being the value produced by deep mines and $1,138,181 that by placers.

As appears from Table 7, there were approximately 3 salaried officials, clerks, etc., to an average mine of incorporated ownership, whereas only 1 mine in 4 of those owned by unincorporated operators had even 1 salaried employee; evidently at the mines of unincorporated owners the work usually done by salaried employees was performed by the operators themselves. It is worthy of note that notwithstanding the large number of mines under corporate ownership, the gold and silver mining industry remained under local control. The location of the general office of the mine may be taken as a test. The following statement shows the number of mines with general offices in the principal business or mining centers and those whose offices were located in other cities or towns, or at the mine:

Location of general offices of mines by cities: 1902.

LOCATION OF GENERAL OFFICE.	All mines.	Producing.	Development work without production.
Total	6,244	2,992	3,252
San Francisco	212	133	79
Salt Lake City	249	77	172
Denver	278	136	142
New York	136	53	83
Boston	73	34	39
All others	5,296	2,559	2,737

The number of companies with general offices in large business or mining centers was considerably short of the total number of incorporated companies. Moreover, those with offices in San Francisco, Salt Lake City, or Denver were likewise mostly local concerns whose mines were situated within the same state. This was equally true of producing and of developing mines, which fact appears from the following statement:

General offices, whether within or without the state where the mine is situated: 1902.

LOCATION OF GENERAL OFFICE.	LOCATION OF MINE.	
	Within the state.	Without the state.
San Francisco	159	53
Salt Lake City	192	57
Denver	262	16
Total	613	126
Producing	328	65
Developing	285	61

The few producing mines with eastern offices in New York and Boston had but a very small part in the gold and silver mining industry in 1902. Their aggregate product amounted to $4,122,206—5 per cent of the total for the United States—and the average product per company was only $49,000.

Capital stock of incorporated companies.—The capitalization of all incorporated gold and silver mining companies for 1902 is shown in Tables 8 and 9; the former relating to producing mines, the latter to such as reported development work only for the year 1902.

A comparison of the results shown in Tables 8 and 9 shows that the amount of outstanding stock and bonds of the companies which reported only development work in 1902 was greater than that of the companies reporting production, viz, $1,173,300,352 for the former as compared with $1,024,970,643 for the latter. The share of placers in the total outstanding capitalization of producing mines amounted to $68,005,794, or 6.6 per cent, while that of deep mines was $956,964,849.

The division of stock into common and preferred is not customary with gold and silver mining companies. In 1902 there were 77 companies having preferred stock, the par value of that issued being $23,804,445. This was only 1 per cent of the total outstanding capitalization of producing mines.

Assessment companies, once a prominent feature in gold and silver mining, are less conspicuous to-day. There were, in 1902, 250 assessment companies, of which 99 operated producing and 151 nonproducing mines. The amount of assessments levied since organization by the former was $21,200,119, and by the latter $31,657,563, a total of $52,857,682, representing an addition of 2 per cent to the total outstanding capital stock and funded indebtedness. The greater part of this amount, $42,966,822, was reported from Nevada, where assessments are still among the favorite means of raising funds for investment in gold and silver mining.

The issue of bonds was little favored, the total amount issued on producing and developing mines being only $10,120,741. The following statement shows the distribution of incorporated companies by the class of stock authorized and issued:

Incorporated companies, grouped by class of stock: 1902.

CLASS OF STOCK.	Number of incorporated companies.	AUTHORIZED.			ISSUED.		
		Total.	Common.	Preferred.	Total.	Common.	Preferred.
Operating producing mines: Total	1,079	$1,213,420,117	$1,194,317,427	$19,102,690	$1,017,011,793	$1,002,055,596	$14,956,197

Wyoming	68	65,105,000		
Placer mines not classified by states			36	35,115,000

There were in all 136 companies by which dividends were paid in 1902; of these 121 operated deep mines and 15 placer mines. The following statement shows the capitalization and dividends of all dividend paying companies and also the capitalization of the companies which paid no dividends in 1902.

The statement shows that the average par value per share of stock varied, ranging from a minimum of $1.47 for nondividend paying common stock to a maximum of $3.61 for dividend paying preferred. There was no material difference between the average par value of stock authorized and issued for dividend paying and nondividend paying companies, although the average for the former was somewhat higher than for the latter. Of the 136 companies which paid dividends in 1902, 4 paid them on preferred stock only. Their authorized capital stock was $3,925,000, of which $2,400,000 was common and $1,525,000 was preferred. The outstanding common stock amounted to $2,150,000 and the outstanding preferred to $1,457,632. The amount paid in dividends on preferred stock was $93,285. One company, with an authorized capital stock of $9,864,600, of which $5,918,800 was common and $3,945,800 was preferred, all being issued, paid in dividends $236,752 on common and $236,748 on preferred stock.

The average rate of dividends on common stock was 5.5 per cent and on preferred 6.1 per cent. One hundred and thirty-one other companies had only one

class of stock upon which dividends were paid. There were 21 companies authorized to issue bonds of a total par value of $9,839,200; the bonds were issued of a par value of $7,958,850. The average value of bonds per share of stock authorized was $22.08 and per share issued, $26.88. The total amount of interest paid was $409,392, averaging 6 per cent. None of these 21 companies paid dividends on its stock.

Capitalization of dividend paying and nondividend paying companies with dividends and interest paid: 1902.

The following is a statement of dividends paid by incorporated companies in 1902 and 1884, compared with the production of the precious metals for the same years:

YEAR.	Number of mines.	Amount of dividends.	Gross value of the precious metals (commercial).
1902[1]	136	$10,454,744	$85,223,732
1884[2]	54	7,567,698	72,870,000

[1] Exclusive of Alaska.
[2] Report of the Director of the Mint on the Production of the Precious Metals in the United States, 1884, page 14.

A summary of dividend and nondividend paying companies is presented in Table 11. It must be borne in mind that the payment of dividends in a given year is not indicative of net profits earned during the same year, for dividends may be paid from the accumulated surplus of former years. Among the 136 companies which paid dividends were 15 whose expenditures, mostly for development work, during the year exceeded their receipts. The dividends declared by these companies aggregated $615,149, out of a total product valued at $1,059,617. It is obvious that these dividends had no relation to the earnings of the year. Likewise, the failure to declare a dividend does not necessarily show actual loss. Earnings may have been invested in development work, in new equipment of plants, in acquiring new property, etc. It is fair to assume, however, that generally the payment of dividends is a sign of successful operation. To facilitate comparisons, all incorporated companies are arranged under three heads: (1) Dividend paying—that is, companies that paid dividends during 1902; (2) nondividend paying companies owning productive mines; (3) developing and producing companies, meaning companies with which production was merely incidental to development work, expenditures being in excess of receipts.

TABLE 11.—SUMMARY FOR DIVIDEND PAYING AND NONDIVIDEND PAYING COMPANIES, BY CLASSES OF MINES: 1902.

	ALL MINES.				DEEP MINES.				PLACER MINES.

Value of product at mine	$68,327,754	$35,307,932	$31,578,495	$1,441,327	$65,831,994	$34,311,515	$30,220,570	$1,299,909	$2,495,760	$996,417	$1,357,925	$141,418
Average per mine	$63,325	$259,617	$51,431	$4,381	$71,247	$293,261	$56,487	$4,779	$16,102	$52,443	$17,189	$2,481

The preceding table shows that the dividend paying companies contributed over one-half of the output. Taking deep mines alone and eliminating companies with which production was merely incidental to development work, it will be observed that the grade of ore mined by dividend paying companies was worth $14 per ton, whereas the ore mined by nondividend paying companies was worth only $7.

Employees and wages.—The average number of wage-earners employed in gold and silver mines was 47,905 men, of whom 33,821 were employed in deep mines, 2,321 in placer mines, and 11,763 in mines reporting only development work. Their total wages amounted to $47,658,176. In any analysis of these figures it must be borne in mind that the above number of wage-earners is an average, computed on the basis of 300 working days, and is not identical with the actual number of persons who earned the amount of wages reported. The average per wage-earner accordingly represents the cost of one man's labor to the employer, which is not identical with the average annual earnings. For the purpose of estimating the earning capacity of wage-earners, average daily rates should be consulted.

The following table shows the distribution of wage-earners according to daily rates of pay for the several classes of employees:

TABLE 12.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

[1] Less than one-tenth of 1 per cent.

As shown by the above table, practically all of the wage-earners in gold and silver mines received $2 per day or over. When the figures for the several classes are combined it is found that 93.3 per cent of the total number received between $2 and $4.24. The statistics show a very large concentration of the wage-earners in three rate groups, as follows: 13.9 per cent of the total number in group $2.50 to $2.74, 33.4 per cent in group $3 to $3.24, and 21 per cent in group $3.50 to $3.74. Most of the employees included in these groups probably received the even rates $2.50, $3 or $3.50 per day.

More than half of the wage-earners were returned as miners. Their wages ranged between narrow limits, 87.2 per cent of the total number having been paid from $2.50 to $3.74 per day. In the rate group $3 to $3.24 are included 36 per cent of all the miners reported. There were also 3,864 men returned as miners' helpers, about one-seventh the number of miners. The rates of pay for these helpers were somewhat lower than those paid to the miners.

The rates paid to engineers, machinists, and other mechanics were higher than those of the other wage-earners; 92.8 per cent of the engineers and 86.9 per cent of the machinists and other mechanics received $3 per day or over. At $4 or more the respective proportions were 42.2 and 37.6 per cent. The rates for firemen were somewhat lower, a much greater proportion of them having been paid less than $3 per day. The range of wages for 79.1 per cent of the firemen was from $2.50 to $3.74 per day. There were 574 timbermen and track layers reported, all but 8 of whom received $2.50 per day or more. The daily rates for the great part of these employees were probably $3 or $3.50, as 33.3 per cent of them are included in the group $3 to $3.24, and 36.6 per cent in the group $3.50 to $3.74.

The boys under 16 years employed in gold and silver mines numbered only 33, and constituted less than one-tenth of 1 per cent of the total number of wage-earners. Five of these boys received less than 50 cents a day, and the rest of them were paid between 50 cents and $2.24.

The group of "all other wage-earners" includes 9,279 men who were not reported under the more spe-

cific heads. The rates of pay for these employees were somewhat lower than those for the wage-earners already considered, about one-fifth (21.8 per cent) having been paid less than $2.50 per day. The majority of them, however, received at least $2.50 and a large proportion received considerably more than that. The group showing the greatest number of employees is that from $3 to $3.24; in that one group are included 34.5 per cent of all the wage-earners in this class.

Table 13 shows the distribution of wage-earners according to daily rates of pay for those states which employed on the average more than one thousand wage-earners. In addition to the number included in each rate group, the percentages which these numbers form of the state total are given and also the cumulative percentages which show for each rate the proportion of the total number receiving that rate or more.

TABLE 13.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY STATES AND TERRITORIES: 1902.

[Each cumulative percentage shows the proportion of the total number receiving a wage as great as, or greater than, the lowest wage of the given wage group.]

[1] Less than one-tenth of 1 per cent.

Of the states for which statistics are presented separately in the above table, rates were highest in Montana. Practically all of the wage-earners in that state received at least $3 per day, and 82.3 per cent of them were paid $3.50 or over. In the single group $3.50 to $3.74 are included 65.8 per cent of all the wage-earners and a large proportion of these probably received exactly $3.50 per day.

In South Dakota, Idaho, and Nevada the rates paid were somewhat less than in Montana, but between the three states there was, on the whole, comparatively little difference. At first glance it would seem that of the three states rates were highest in Nevada, for that state shows an exceptionally large proportion of wage-earners at $4 and over. It will be noticed, however, that the proportions at $3 or more and at $3.50 or more are greater in South Dakota and Idaho than in Nevada, while the proportions receiving less than $3 are smaller. Of the wage-earners in South Dakota, 53.9 per cent are included in the single group $3.50 to $3.74, and 31 per cent in the group $3 to $3.24. In Idaho 86 per cent are included in three

consecutive groups, constituting the range from $3 to $3.74 per day. There was a greater divergence in the wages paid in Nevada, the group including the greatest number of employees being that from $3 to $3.24, and the one including the next largest number being that from $4 to $4.24.

Following the states above mentioned in the order of the rates paid come Colorado and Arizona. In these two states, also, there was on the whole comparatively little difference in wages. In Colorado the range of wages for 94.2 per cent of the wage-earners was from $2.50 to $4.24 per day, 48.3 per cent being included in the single group $3 to $3.24. In Arizona the wage-earners were distributed in smaller groups over a wider range. Practically all of them (97.1 per cent) received between $1.50 and $4.24 per day. The greatest concentration in Arizona is at $3 to $3.50 per day, 23.7 per cent being included in group $3 to $3.24 and 33.4 per cent in group $3.50 to $3.74.

Of the states which employed, on the average, more than one thousand wage-earners, California and Utah show the lowest rates. In each of these states the greater part of the wage-earners received between $2.50 and $3.24 per day, the proportion included between those limits being 76.4 per cent for California and 78.3 per cent for Utah.

It will be noticed that the statistics grouped under "all other states and territories" include practically all the returns for wage-earners receiving less than $1.50 per day. This is due to the inclusion of several Southern states, in which rates of wages were low. They reported a comparatively small number of wage-earners. The employees at the higher rates included under "all other states and territories" were principally in Oregon, New Mexico, and Washington, where rates were approximately the same as in the Western states, for which a separate showing is made in Table 13.

In addition to regular wage-earners employed by the day or by the task, there is a special class of labor variously designated as "leasers," "block lessees," "tributers," "chloriders," etc. Technically, they "lease" from the operator a block in the mine and "pay" a stipulated royalty, which varies with the richness of the ore; in reality all the ore hoisted is usually delivered to the operator and marketed by him, or else it is shipped in his name to the sampler or smelter; the operator retains his royalty, or authorizes the ore buyer to withhold the same, and pays to the "lessees" their share of the proceeds. In all cases these workers furnish their own mine supplies. While resembling in form an ordinary mining lease, this is in substance a contract of employment on a share of the product.

The average number of miners employed on a share of the product in 1902 was 1,280, and the total compensation received by them amounted to $1,452,692, which included the cost of supplies furnished by them. This system is in vogue chiefly in Colorado, which reported 158 mines worked on shares, with 823 "leasers." California had 27 such mines; Montana, 18; Nevada, 7; Idaho, 3; New Mexico, 3; Arizona, 3; Oregon, 2; and Georgia and North Carolina, 1 each.

A summary of mines employing this class of labor is presented in the table next following. Deep mines are divided into two groups—those worked on shares only and those employing both share and wage workers. There were only 2 placer mines reported as having both classes of labor; these 2 mines are therefore omitted from the table. The mines worked exclusively on shares were small. The larger mines where this system was practiced also employed regular wage-earners.

TABLE 14.—*Summary for mines worked on shares: 1902.*

	DEEP.			PLACER.
	Total.	Without wage labor.	With wage labor.	Without wage labor.
Number of mines	203	162	41	18

Average per ton	$15	$18	$14	.....
Value of product at mine	$3,585,254	$728,885	$2,856,369	$88,105
Average per mine	$17,661	$4,499	$20,258	$4,895

There are a number of gold and silver mines in which manual labor is performed by the owners, either with or without the assistance of hired help. The total number of owners so employed in producing mines was reported as 1,495 and the number so engaged in mines under development was 609. There were in all 599 producing mines and 281 under development which employed no hired labor at all. It must be borne in mind, however, that the census agents were instructed to omit from their canvass mines where less than two wage-earners were employed. The above numbers, therefore, include only such mines as were reached by correspondence and those which were supposed from preliminary information to come within the scope of the canvass, but were found upon personal inquiry by special agents to employ no hired labor. The total number of men engaged in working their own mines without hired labor, or with but casual help, must be considerably larger than the number reported.

A summary for mines operated without hired labor, as far as reported, is presented in the following table:

TABLE 15.—*Summary for mines operated without hired labor: 1902.*

	Total.	Placer.	Deep.
Number of mines	599	396	203
Number of owners working	1,165	774	391
Contract work	$1,685	.....	$1,685
Miscellaneous expenses, total	$31,094	$18,557	$12,537
Rent and royalties	$26,057	$15,100	$10,957
Mines and mineral lands	$18,966	$8,312	$10,654
Water	$2,536	$2,317	$219
Other	$4,555	$4,471	$84
Other miscellaneous expenses	$5,037	$3,457	$1,580
Cost of supplies and materials	$41,745	$21,248	$20,497
Ore sold or treated, short tons	9,332	.....	9,332
Average per deep mine	46	.....	46
Total gross value	$528,496	$293,176	$235,320
Average per ton	$25	.....	$25
Treatment charges and freight	$45,928	$1,407	$44,521
Value of product at mine	$482,568	$291,769	$190,799
Average per mine	$806	$737	$940

The average output per mine, as shown in the preceding table, was less than one thousand dollars; the output of ore in an average deep mine operated without hired labor was 46 tons, and there were about two owners working in an average mine. It is evident that the work did not occupy the entire time of the owners. This must be borne in mind if it is desired to make comparisons with other mines. Ore bringing $25 per ton is considered a high-grade product.

The mines at which owners were reported to be doing manual labor include cooperative mines, the number of which was 25. Of this number there were 11 mines each of which reported less than five men employed.

The term "cooperative" as applied to such mines is somewhat vague. A "cooperative association" consisting of from two to four men, often working by turns and devoting to the work only such time as can be spared from other occupations, is not easily distinguished from an ordinary partnership. If 5 members be considered the minimum for a cooperative association, there were 14 such associations, with 171 working members; in addition to these, 1 man was hired for wages. Of these associations, 1 with 12 working members was incorporated, with a capital stock of $60,000, and upon this capital a dividend of 6 per cent was paid. This mine is also included among those owned by incorporated companies. The greatest number of men reported by a single association was 23. Twelve associations, with a combined membership of 136 men, were engaged in placer mining, and 2 with 35 men were operating deep mines. The membership of these associations included 101 Chinese and 70 persons of all other nationalities. The Chinese were working exclusively in placer mines. There were in all 8 associations composed exclusively of Chinese, with a total membership of 95 men; the greatest number reported by any Chinese association was 16. There were 5 associations, with a total membership of 68 men, composed of other nationalities and 1 with a mixed membership.

The total output of all cooperative associations was valued at the mine at $92,313, averaging $6,594 per mine. The mines are grouped by the value of production, as follows: One with an output of less than $500; 3 with an output exceeding $500 but less than $1,000; 7 with an output exceeding $1,000 but less than $10,000; and 2 with an output exceeding $10,000 but less than $50,000.

Contract work.—An amount of contract work in and about the mines was done by individuals, firms, and companies making a specialty of certain classes of work. The total amount paid for contract work was $2,168,861, of which $1,542,771 was paid at mines where development work alone was prosecuted, and $626,090 at producing mines. The latter amount was nearly all expended in development work, such as tunneling, shaft sinking, drifting, running levels and winzes, etc. Mining proper (stoping) was only in two cases reported as being done by contract along with development work, the total expenditure for contract work in these two cases amounting to $46,888. Pumping was reported in two cases only, the total amount being insignificant. In a few cases cutting and hauling of wood and timber, roadmaking, and building and cleaning of ditches were reported, the total expense amounting to $15,414.

The number of men employed on contract work could not always be stated accurately by mine operators, for the reason that they had no direct control over the men employed by the contractors. Very frequently the number of men to be furnished by the contractor was stipulated in the contract. Still the time consumed by them in doing the work was in most cases not stated; therefore the number of men could not be reduced to an annual average basis of 300 working days, and duplications could not be avoided. The same men working in a mining camp on a number of mines successively were reported by several operators. The total number reported for producing mines was 980 men, whereas in mines reporting development work only, the number of men employed by contractors aggregated as many as 5,649. The number of men reported in each class of mines shows an extreme disproportion to the amounts paid for contract work. It is apparent that in some cases the number of men must have been underestimated, whereas in others there were probably many duplications.

The several classes of labor presented under the head of "employees and wages" and "contract work" comprise an average of 47,905 regular wage-earners, 1,280 workers for a share of the product, 2,104 owners doing manual labor, and 6,629 men employed by contractors. In addition to these, 5,135 prospectors reported 5,519 mining claims, upon which, in compliance with the mining laws, the sum of $551,900 ought to have been expended in assessment work. Considering that many mines were operated only at certain seasons and that during a portion of the year the miners had to employ their time in other industries, it may be conservatively estimated that from 50,000 to 60,000 men found employment in gold and silver mining.

Time in operation.—Tables 16, 17, 18, 19, and 20 present a classification of producing mines by the number of days in operation, number of shifts employed per day, and number of hours per shift, and a like classification of all mills whenever separately reported.

For a number of the mills combined with mines only one report was made for both mill and mine, in which case the report was included with the number of mills. There were, as stated on a preceding page, 599

mines in which no hired labor was employed, not including 162 mines where all miners were working on a share of the product, and 2,393 mines and mills with regular wage-earners. Many of the two former classes failed to report the number of days and hours in operation. The number of mines reporting the days in operation was 2,525, and the number reporting the hours in operation was 2,494. The total number of mines shown in Tables 18 and 19 includes a duplication of 34 mines which reported different hours for various classes of employees. All other mines reported the same hours for all employees.

Supplies and materials and miscellaneous expenses.—The general term "materials" has scarcely any application to mining. The "material" operated upon in a mine is the rock underground or the gold bearing gravel. The inquiry calling for "total cost of supplies and materials of all kinds used during the year" at the mine contained the following explanatory note:

"The cost of the following materials should be reported under this inquiry: Lumber and timber used for repairs, mine supports, track ties, cars, and for all other purposes; iron and steel for blacksmithing; rails, frogs, sleepers, etc., for tracks and repairs; parts of machinery and tools used for renewals and repairs; explosives, water for boilers and for other purposes; fuel, illuminating and lubricating oils, machinery supplies, etc."

All the items here enumerated come strictly under the definition of "supplies." The "material" treated at the mills is the ore which comes from the mine. It is not customary in mining bookkeeping to charge the mill with the value of the ore brought from the mine. In the schedule relating to "reduction works, other than smelters," there were two separate inquiries, one relating to "materials," another to "supplies." The former called for a statement of the "character of materials used, whether ore, tailings, or other materials," and was confined to "materials bought in 1902." The amount reported in answer to this inquiry is not included in the cost of "supplies and materials" but is given elsewhere as a separate item.

The explanatory note to the inquiry relating to mill "supplies" enumerated: "Shoes, dies, screens, plates, and other parts of machinery and tools used for renewals and repairs; quicksilver, cyanide of potassium, lumber, iron, steel, oil, fuel, water, etc."

The total cost of "supplies and materials," as herein defined, was reported as $21,774,845, distributed as follows: Producing mines, deep, $15,908,782; placer, $790,986; developing mines, $5,075,077.

The item, "miscellaneous expenses," includes rent and royalties of all descriptions, "taxes, insurance, interest, advertising, office supplies, law expenses, injuries and damages, telegraph and telephone service, gas, and all other sundries not reported elsewhere."

The total amount of miscellaneous expenses of producing mines was $5,357,529, of which $1,419,155 was reported as rents and royalties of all descriptions for mines, and $3,938,374 for all other mine expenses and miscellaneous mill expenses; the latter item includes the sum of $4,244 paid by custom mills as royalties for the privilege of reworking old tailings.

The miscellaneous expenses of developing mines aggregated $1,017,356, of which rents and royalties of all descriptions amounted to only $71,131. That the amount of rents and royalties paid by this class of mines was so insignificant is in harmony with the character of the mines, royalties and rents being as a rule proportionate to the returns of the mine. Where the mine is not producing, the labor and expense incurred by the operator in developing the mine are a part consideration for the privilege of working the same.

Of the items making up the total royalties ($71,131), the principal expense ($41,916) was for the use of water, and the next largest sum ($16,153) was expended for electric power; other power (air, steam, etc.), cost $2,406; the rents of mines and mineral lands amounted to $4,528; expenditures on plant and improvements were $3,572; for tunnel privileges, $843; and rent of office and miscellaneous rents, $1,713.

The following is a statement of rents and royalties paid by producing mines:

Rents and royalties paid by producing mines: 1902.

	All mines.	Deep.	Placer.
Total	$1,419,155	$1,273,388	$145,767
Mines and mineral lands	696,372	649,565	46,807
Plant and improvements	84,721	80,544	4,177
Tunnel privileges	64,282	64,257	25
Water rent	287,010	243,346	43,664
Electric power	215,802	165,916	49,886
Air and steam power	2,111	2,111	.....
Miscellaneous rents	68,857	67,649	1,208

The greater part of the royalties paid for the use of the mines and mineral lands, $500,550, was reported from Colorado; the amount reported by all other states was only $195,822. Royalties for tunnel privileges were reported as follows: Colorado, $43,954; Nevada, $12,482; Utah, $7,266; all other states, $580. The most of the payments for water rents, $210,641, was reported from California; the next largest sum, $40,707, was reported from Colorado, while all other states aggregated $35,662. The amount expended for rent of electric power was $215,802, of which $128,077 was reported from California and $87,725 from Colorado. The rent of other power was exceptional.

The royalties do not include those charged to so-called "block lessees," "tributers," etc., who made no reports to the census. Where the mine was worked by regular wage-earners as well as by tributers the amount charged against the latter as royalties could not be segregated. But where this was the only class of labor employed in mining the amount charged as royalties can be ascertained by deducting the amount paid to the lessees from the total value realized for the ore at the mine.

Mineral lands.—The primary distinction between mining and manufacturing is that in the latter only capital and labor are factors, while in the former industry there are three factors of production, viz, land, capital, and labor. The present census of mines and quarries is the first in which the scope of the inquiry has in some branches been extended to the ownership of mineral lands. Though the special schedule providing for gold, silver, lead, and copper mines confined itself to mineral lands, it is probable that in some cases the reports included lands of all descriptions, such as timbering lands, building lots, etc.

The acreage of mineral lands was reported for 5,845 mines, viz: Producing, deep, 1,913; producing, placer, 846; mines in the development stage, 3,086. No report of acreage was made for 178 producing, and for 166 developing, mines; these constituted 5.5 per cent of the total. The area reported by producing mines was 406,009 acres, of which 219,349 acres belonged to deep mines and 186,660 acres to placers; 653,001 acres were reported by mines under development. This shows that the area held for development exceeds by more than one-half the acreage of producing mines.

The leasing of mineral lands had only a subordinate part in gold and silver mining. The total area rented was 58,807 acres, 33,259 acres by operators of producing mines and 25,548 acres for development. The total royalties paid for the use of mineral lands amounted to $696,372, of which $46,807 was paid on placers and $649,565 for deep mines. In Table 21 all mines reporting acreage are arranged by the area owned and leased, by the character of mine, and by states and territories. The number of mines contains a duplication of 68 mines which were located on land partly owned and partly leased.

The preceding table shows the concentration of the ownership of mineral lands, both in deep and placer mines. By far the greater part of all mineral lands is held in plots of 100 acres or more, representing an aggregation of five or more original locations. This concentration is especially conspicuous in mining properties which are now being developed; four-ninths of all such mineral lands are held by 52 operators. One mining property in California extends over an area of 100,000 acres.

The correlation between the area of mineral lands and value of production is shown in the following table:

TABLE 22.—*Classification of deep and placer mines by acreage and value of product: 1902.*

	Number of mines.[1]	ACREAGE. Total.	ACREAGE. Per cent.	VALUE OF PRODUCT AT MINE. Total.	Per cent.	Average per mine.	Average per acre.
Deep and placer mines	2,937	406,009	100.0	$78,151,089	100.0	$26,609	[2]$188
20 acres or less	921	13,644	3.4	7,476,142	9.6	8,117	548

[1] Exclusive of 55 custom mills.
[2] The product on which this average is computed does not include that for mines which do not report acreage.

It appears from the preceding table that the value of the mining product bore no direct relation to the area of mineral lands owned or leased. The average production per acre decreased as the area increased; the three owners of the largest acreage were among the smallest producers. It is probable that while the smaller properties were under active operation the larger were awaiting development. Still the value of the average production per mine increased with the increased ownership of mineral lands, though not in the same ratio.

The following table shows in parallel columns the royalties paid and the value of product of deep mines operated on leased land only. It covers 10,872 acres, i. e., 78 per cent of all lands leased by deep mines. Operators, 55 in number, who owned mineral lands in addition to the lands leased are omitted.

TABLE 23.—*Value of product and royalties of deep mines operating on leased land only: 1902.*

STATE OR TERRITORY.	Number of mines.	Value of product at mine.	RENT AND ROYALTIES FOR MINERAL LANDS. Total.	Per cent of product.
United States	330	$3,240,986	$510,818	15.8
California	30	188,547	18,195	9.7
Colorado	193	2,190,840	379,521	17.3

Utah	16	111,145	5,460	4.9
All other states and territories[1]	10	24,332	7,481	30.7

[1] Includes Arizona, 2; Maryland, 1; North Carolina, 1; Oregon, 3; Virginia, 2; and Washington, 1.

The following is a summary of all the statistics for deep mines operated on leased land only:

TABLE 24.—*Summary for deep mines operated on leased land only: 1902.*

Number of mines	330
Number of owners working	139
Salaries	$195,917
Wages	$1,504,855
Contract work	$70,399
Work on share of product	$28,581
Rent and royalties of mines and mineral lands	$510,818
Other miscellaneous expenses	$110,132
Cost of supplies and materials	$590,914
Ore sold and treated, short tons	267,555
Value of bullion contents:	
Gold	$2,716,755
Silver	$1,187,171
Other metals	$601,386
Total gross value	$4,505,312
Average per ton	$17
Value of product at mine	$3,240,986
Average per mine	$9,821
Acreage leased	10,872
Average per mine	33

Mechanical power.—The total primary power used in gold and silver mines amounted to 195,805 horsepower, of which 122,354 was steam, 43,936 water, 4,060 gas or gasoline, and 8,003 other power, mostly compressed air. Of this total the rented horsepower aggregated 17,452, of which 14,469 horsepower was electric. In addition 750 electric motors, having a capacity of 32,003 horsepower, were reported owned by the operators. More than one-half of all rented electric power was reported from California, the rest was nearly all used in Colorado.

The use of water as a motive power was a marked feature in California, which reported nearly one-half of all waterpower used, viz, 21,517 horsepower. The total horsepower of steam engines in that state was 16,858, and the total electric power owned and rented was 18,961. Thus water and electric power held a more prominent place in California than steampower.

Nearly all the power reported was used in deep mines; comparatively little was used in placers. The latter utilized chiefly water and electric power. The following table shows the quantity and kind of power used in producing mines, deep and placer:

TABLE 25.—*Power used in producing mines: 1902.*

	Total.	Deep.	Placer.
Total horsepower	195,805	184,512	11,293
Owned:			
Engines—			
Steam—			
Number	1,925	1,805	120
Horsepower	122,354	118,833	3,521
Gas or gasoline—			
Number	198	189	9
Horsepower	4,060	3,940	120
Water wheels—			
Number	788	686	102
Horsepower	43,936	40,206	3,730
Other power—			
Number	156	150	6
Horsepower	8,003	7,588	415
Rented:			
Electric, horsepower	14,469	10,982	3,487
Other power, horsepower	2,983	2,963	20
Electric motors owned:			
Number	750	607	143
Horsepower	32,003	27,758	4,245
Supplied to other establishments, horsepower	323	223	100

Over one-fourth of all deep mines and the bulk of the placer mines had no other motive power except hand and animal power. The aggregate product of the deep mines operated in this primitive way was very small, as compared with the total product of deep mines, being valued at only $1,730,469, or 2 per cent. In placer mining, however, the reverse was the case, the major part of the placer product of the United States being obtained without mechanical power.

The following table is a summary of deep mines which used no mechanical power. Regular producers are segregated from mines, the operations of which consisted mainly of development work, to which production was merely incidental:

TABLE 26.—*Deep mines using hand and animal power only: 1902.*

	Total.	Producing.	Developing and producing.
Number of mines	563	330	233
Number of owners working	319	250	69
Salaries	$135,991	$62,247	$73,744
Wages	$1,144,414	$616,835	$527,579
Contract work	$60,041	$21,206	$38,835
Work on share of product	$175,988	$172,900	$3,088
Miscellaneous expenses	$145,217	$113,959	$31,258
Cost of supplies and materials	$282,432	$149,858	$132,574
Ore sold and treated, short tons	116,435	101,528	14,907
Gross value of product	$2,485,978	$2,221,421	$264,557
Average per ton	$21	$22	$18
Value of product at mine	$1,730,469	$1,557,438	$173,031
Average per mine	$3,074	$4,719	$742

The following table is a comparative summary of placers according to the power used, whether mechanical or other:

TABLE 27.—*Placer mines using mechanical or other power: 1902.*

	Total.	Mines with mechanical power.	All other.
Number of mines	[1] 967	155	812
Salaries	$318,313	$204,191	$114,122
Wages	$1,769,612	$826,826	$942,786
Contract work	$19,816	$14,318	$5,498
Work on share of product	$73,517	$33,153	$40,364
Miscellaneous expenses	$271,844	$179,832	$92,012
Cost of supplies and materials	$781,236	$531,363	$249,873
Value of product at mine	$4,058,189	$2,115,722	$1,942,467
Average per mine	$4,197	$13,650	$2,392
Method of treatment:			
Dredging [2]	45	45	
Hydraulicking	471	52	419
Other methods	451	58	393

[1] Does not include 8 mines with stamp mills.
[2] Includes 1 mine using electric elevator.

The following is a comparative table of steam engines and horsepower reported for 1902, 1889, 1880, and 1870. The previous censuses did not distinguish producing mines from those where the work was confined to development; the results for 1902, in Table 28, therefore, combine both classes of mines. While the total horsepower used shows a remarkable increase, the average power per engine has remained practically the same. In 1870 it was 44 horsepower; in 1880, 46 horsepower; in 1889, 40 horsepower; and in 1902, 55 horsepower.

The total number of hoists in producing mines reported was 1,249, of which number 968 were operated by steampower, the rest by other mechanical power. Aside from the 563 deep mines which used only hand and animal power, there were a number of mines which were reached by tunnels or adits at which hoists could be dispensed with. The following comparative table shows the number of steam hoists used at all deep mines, producing as well as those reporting development work without production, in 1902 and 1880:

TABLE 30.—*Steam hoists at deep mines, by states and territories: 1902 and 1880.*

The total number of pumps used in 1902 was 1,261, of which number 1,059 were operated by steam and 202 by other power. Of this number, 769 were used in producing deep mines, 71 in productive placers, and 421 in mines under development. Some mines are drained by tunnels. The total number of producing deep mines being 2,017, it is apparent that a great many mines were not troubled with water and could therefore dispense with pumping machinery.

A noteworthy feature is the development of the use of power other than steam for operating pumping apparatus. In 1880 there were in all 4 pumps operated by water and 1 by compressed air; in 1902 the number of pumps operated by compressed air had increased to 97, the number operated by water to 42, and in addition 49 were run by electric power and 39 by gas or gasoline.

The following table shows the number of power drills at all deep mines in 1902 and 1880, by states and territories:

TABLE 32.—*Number of power drills at deep mines, by states and territories: 1902 and 1880.*

The total number of power drills reported at producing mines in 1902 was 2,499, of which number 2,297 were operated by compressed air, 167 by steam, 31 by electricity, and 4 by water. Power drills were used in 353 mines. Among them were 5 placer mines, with a total of 12 drills, used in working ancient river beds by drifting; of the number reported, 5 were not in use during the year 1902. Comparison with the Tenth Census shows a remarkable progress in the use of power drills. In 1880 there were in all 257 power drills in use; in 1902 the number was 3,329.

The comparative results of working with power drills and by hand are shown in Table 33. Only deep mines are included; 26 mines using power drills fur-

nished incomplete information on the subject and are therefore omitted.

TABLE 33.—*Comparison of power drills and hand power at deep mines: 1902.*

	All mines.	Mines using power drills.	Mines using hand power.
Number of mines	1,909	322	1,587
Number of drills used	2,358	2,358	
Tons of ore mined in 1902:			
Total	9,966,406	7,340,536	2,625,870
Average per mine	5,220	22,797	1,655
Wages below ground	$24,268,800	$14,991,375	$9,277,425
Average wages per ton	$2.43	$2.04	$3.53

The preceding table shows that three-fourths of the total quantity of ore came from mines using power drills. The average product per mine with power drills was 22,797 tons, whereas the average per mine where no power drills were used was only 1,655 tons. The saving in labor below ground effected by the use of power drills, as compared with mining by hand, amounted to $1.49 per ton.

Of the machinery especially designed for placers, dredges were used in 44 mines. There were also 32 steam shovels in use, of which 21 were used in producing placer mines, and 11 in mines at which development work only was done.

The majority of deep mines have adopted mechanical power for conveying their ores to the reduction works; a very large number, however, still adhere to the old-fashioned way of carrying the ore in wagons. The former numbered 1,182 and the latter 925. The length of railroad tracks on the surface was 168 miles; underground, 945 miles. The number of locomotives was reported as 49. Of this mileage, 3 miles on the surface and 25 underground were reported for placer mines which were operated by drifting.

Water plants.—An abundant supply of water is one of the prime conditions of successful mining, especially in placers. The gold and silver mines were equipped with extensive water plants, which included 3,927 miles of ditches, flumes, etc.—2,992 miles for placer mines, or an average of over 3 miles per mine, and 935 miles for deep mines, or less than one-half mile per mine. The following table shows the length of water ditches, flumes, and pipes, by states and territories, for placer and deep mines:

Production.—The value of the total production of gold and silver mines in continental United States in 1902 was $82,482,052, of which $77,154,326 was produced by deep mines and $5,327,726 by placer mines. In determining the value of the product at mine, the method of valuation adopted in the mining industry was followed by the census. The value of the ore and bullion is determined in accordance with a well established trade custom, in the following manner: The ore is sampled and assayed, and the price per ton is determined in accordance with the assay contents. Gold, if exceeding in value $1 per ton, is paid for at the coining rate of $20.67 per ounce, or very often at the commercial rate of $20 per ounce; sometimes a further discount of 5 per cent is made, i. e., of $1 per ounce to cover losses in reduction. Silver is paid for at the New York market quotation, usually with a discount of 5 per cent for losses in smelting. Lead is paid for at the New York quotation, usually with a discount of 10 per cent for losses in smelting, and with a further reduction of 2 cents per pound of fine lead contents for freight to New York. Copper is paid for at a stipulated price, depending upon the New York quotation, but usually from 4 to 6 cents below the same; an allowance is made for iron and manganese, if present in sufficient quantities; no allowance is made for zinc, but on the contrary a penalty is charged if the percentage of zinc exceeds a fixed maximum. After the gross

price per ton has thus been determined a stipulated charge per ton is deducted for sampling, assaying, and treatment, and the balance represents the value of the ore at which the total value of the shipment is computed.

The freight charges for carrying the ore from the mine to the works are borne by the mine operator. Usually the freight is paid by the buyer and deducted from the agreed value of the shipment, and a check for the balance is delivered to the mine operator. Thus, as a rule, the value of the ore at mine is not a speculative quantity, but an amount appearing on the books of the mine operator. Where the mine is situated at a distance from a railroad station, the operator usually hauls the ore to the station by his own teams, and the cost of haulage is included in the operating expenses. Where a number of mines are centered in one camp, haulage is more frequently done by teamsters who make a specialty of hauling ore from the mines to the railroad station and bringing back supplies to the mines. Under ordinary circumstances the hire per ton will not vary during the year and can be accurately stated. This is true even if no separate account of it is kept by the operator, in which case the cost of haulage is included in the amount reported for freight. When the ore is of a very low grade, or where the mine is located at a great distance from the railroad station, and the cost of haulage is paid by the mine operator, it sometimes happens that the value realized does not repay the cost of shipping. A few such cases were reported for 1902, and the value of the product was shown as a "net loss."

The value of bullion when sold to the United States mints or assay offices is determined by assay; gold contents are paid for at the coining rate of $20.67 per fine ounce, and the silver contents at a price fixed from time to time by the Director of the Mint; a small charge is made for smelting and refining. When bullion is sold to private parties, banks, bullion dealers, etc., it is usually sold at a net price per crude ounce; the difference between the coining value of the fine gold contents and that paid by the buyer represents the expenses of refining and marketing the bullion, commissions, interest, etc. When the bullion is shipped by express the cost of expressage is deducted by the Mint and the balance is paid to the depositor of the bullion. Frequently bullion is sent by registered mail or brought to the Mint or bullion dealer personally by the owner. The cost of transportation is insignificant as compared with the value of the bullion, and may be treated as a negligible quantity. Thus the value received by the operator for his bullion always represents the value at his mine or works.

The following table shows in detail the manner in which the above-stated total value of the mining product was obtained:

TABLE 35.—*Value of product at mine: 1902.*

Placer mines		$4,188,795
Deep mines and mills connected with same: Ore and bullion sold		71,588,036
Mills operating on old dumps and tailings		361,045
Custom mills: Ore and bullion sold		8,410,854
Amount earned by all mills for custom work		847,334
Estimated value of increase of stock of ore		1,888,408
Estimated product of small mines:		
Placer		1,138,181
Deep		495,654
Total		$88,918,307
LESS.		
Net loss reported by mines	$3,916	
Decrease of stock on hand, estimated value	26,215	
Cost of purchased ores	5,993,915	
Freight paid on purchased ores	412,209	
Total		$6,436,255
Net total		$82,482,052

The values shown for placer bullion and for ore and bullion produced by deep mines and mills represent the amounts reported by the operators. There is a separate item showing the product of the treatment of old dumps and tailings. This represents the output of mills which operated exclusively on old dumps and tailings. The treatment of ore from dumps and tailings, which was incidental to the operations of all mills, is included in their total output.

The ore and bullion sold by custom mills represent only the products of ores purchased by those mills. When the ore was merely treated for a stipulated compensation and the dressed ore (concentrate) or bullion was returned to the owner, the amount earned for the treatment of the ore only was considered as belonging to the production of the mill. The value of the ore or bullion itself was not included in the product of the mill, inasmuch as it would have been a duplication of the value received by the mine owner for his product. Moreover, it was only in exceptional cases that the mill operator was able to report the value of such ores, inasmuch as his charges were not dependent upon the value of the ore and he had no interest to keep an account of the same. On the contrary, the product of the purchased ores was always reported. In order to eliminate duplications, the cost of purchased ores and freight paid on the same are deducted in the preceding statement from the total value reported.

The increase and decrease of the stock on hand represent the differences between the value of the stock on hand at the beginning and at the close of the year. In accounting for the mining production of a given year these differences must be taken into consideration, inasmuch as the product actually sold or treated during the year does not represent the returns for the mining expenses incurred during the same year. In individual cases the difference may be considerable. The value of the increase or decrease of stock of ore is necessarily an estimate. The value was computed at this office, taking as a basis in each case the value reported by the operator for the marketed ore and assuming the average value per ton of the increase or decrease of stock

on hand to have been the same as that of the marketed ore. The decrease of stock represented ore mined in previous years and marketed during the year 1902. Though the grade of that ore may have been different from that of the ore mined during this year, yet for statistical purposes the assumption of one average value for all ore treated was correct. Where there was an increase of the stock of ore, however, it would be often unsafe to assume the average value of the ore on the dumps to be the same as that of the ore actually sold or treated. The ore may have been sorted and the better grade sold, the ore left on the dumps being of a low grade which it would not pay to ship, or a few test shipments may have been made which did not represent the average grade of ore. In order to guard against such errors no estimate was made of the value of the increase of stock whenever the same exceeded the actual quantity sold, unless, upon a comparison of the returns for ore actually sold with the outlay for mining, it appeared probable that more paying ore had been mined than sold and that the ore on hand was merely awaiting treatment. In all doubtful cases inquiries were addressed to the operators, and these, as a rule, were answered promptly and satisfactorily.

Nor were any estimates made of the increase of the stock of ore in cases where the mine was equipped with a mill. When the expenses of the latter were not reported separately there was no basis for estimating the cost of milling the ore, and none but the gross value of the same could be estimated; moreover, the fact that the ore was not milled raised the presumption, at least in some cases, that it did not pay to treat it. Thus the value of the increase of stock of ore is probably rather underestimated than overestimated.

There were a number of small mines, deep and placer, from which no report could be secured. Their output was ascertained from the best available sources, such as assay offices, local bullion dealers, and other reliable persons who, through business intercourse with the miners, had acquired information which enabled them to estimate the output of such mines with reasonable accuracy. These estimates, however, as will be shown later, seem to be below the actual production of this class of mines.

The value thus computed represents the value of the product of gold and silver mines for 1902. It must be understood that many small operators keep no books or records, and the amounts reported by them are approximations.

Bullion contents.—As explained above, the bullion contents of the ore were figured in detail in every settlement between mine operators and ore buyers. The statements rendered by the latter to the former are, in all well managed mines, kept on file and entered in detail in the books of the company. The same is done with United States Mint bullion returns. Not in all cases, however, are accounts kept with such accuracy, even in some of the larger mines. In such cases the bullion contents reported were of necessity estimated. The approximations, however, may be taken as reasonably accurate, inasmuch as the treatment charges did not vary widely for the same mine, while the freight per ton could be regarded as a constant quantity. In some cases the value alone was reported for each of the metallic elements of the ore; the number of ounces of gold and silver, and the pounds of lead and copper were then computed on the basis of the average value reported in other cases.

The total quantity of gold bullion produced by mills connected with mines was 1,666,515 ounces with a gross value of $34,062,535, or an average value of $20.44 per ounce. This was the rate realized by the operator, the difference of 23 cents representing the cost of refining and marketing the bullion. The gross value of the product of mines connected with mills includes the sum of $520,727, which represents net value, the refining charges on the bullion produced not having been reported. At the above average rate the cost of refining the above quantity must have been about $5,207, which, being added to the gross value, would increase the production by 252 ounces. The quantity is too small to be considered.

The number of fine ounces of gold produced by arrastras was not reported. The gross value, the treatment charges, and the net value alone were reported. The quantity was estimated upon the basis furnished by the reports of mines connected with mills.

The total value of the ore at the mine includes $495,654 reported from small mines, whose owners could not be located, and the product had to be ascertained from the best available sources. The amount so ascertained may in some cases have represented the net value realized by the miner for his ore. In others the estimates were apparently based upon the assumption that the values represented the metallic contents of the ore. The number of fine ounces of gold reported apparently represent an estimate at the coining rate of $20.67 per ounce of gold, or at the current commercial rate of $20 per ounce, and at the rate of 50 cents per ounce of silver.

For all these mines the average rate per ounce of gold was $20.17, which left about 50 cents for the cost of refining and marketing. Wherever the estimated value in reality represented net proceeds, this computation resulted in an underestimate of the quantity. Where, however, it represented gross value of metallic contents, it resulted in an overestimate of the net value produced. However, the amount is so small in proportion to the production of the United States that the effect of it upon the total product may be regarded as a negligible quantity.

Most of the placer mines failed to report the number of fine ounces of gold. There were 150 mines, which reported the gross value of the bullion, the cost of

refining and expressage, and the value at the mine, viz, gross value of the bullion contents, $1,621,723; cost of refining and expressage, $9,530; value at mine, $1,612,193. The average cost of refining, etc., amounted to six-tenths of 1 per cent of the value, or 12 cents per ounce, leaving $20.55 as the value realized per ounce of placer gold. All other placer mines from which reports were received numbered 825, with an aggregate product valued at $2,583,272 at the mine. The average value per mine was $3,131, whereas the output of mines reporting charges averaged $10,748 per mine. Apparently the records were more complete with the larger mines. The average shown by them was taken as representing the general condition, and the number of fine ounces where the value only was reported was estimated at the rate of $20.55 per ounce.

Tables 36 and 37 present the bullion contents and the total gross value of the product of the mines and mills for 1902. The product of custom mills is not included, inasmuch as it represents the contents of ore bought from mine operators by whom it was presumably reported.

It is true the quantity treated during the year by reduction works would not exactly coincide with the quantity of ore sold by mine operators to the same class of works during the same year. Still the error is considered immaterial, and in no other way could duplications be avoided.

TABLE 36.—BULLION CONTENTS OF THE PRODUCT OF GOLD AND SILVER MINES CLASSIFIED BY CHARACTER OF MINE: 1902.

	Total value.	GOLD.		SILVER.		LEAD.		COPPER.		Zinc—value.	Other metals—value.[1]
		Fine ounces.	Value.	Fine ounces.	Value.	Fine pounds.	Value.	Fine pounds.	Value.		
United States	$99,093,070	3,149,128	$63,774,881	42,746,064	$21,448,851	411,038,434	$12,311,239	14,028,863	$1,016,204	$340,686	$201,209
Placer mines	5,343,176	259,143	5,340,087	4,303	2,235						854
Deep mines:											
Total	93,749,894	2,889,985	58,434,794	42,741,761	21,446,616	411,038,434	12,311,239	14,028,863	1,016,204	340,686	200,355
Mines without mill connection	34,226,861	1,058,964	21,197,571	20,160,820	10,140,531	87,026,083	2,149,356	6,468,663	508,324	166,767	64,312
Mines combined with mills	59,027,379	1,815,482	36,924,616	22,317,525	11,175,262	322,708,401	10,109,749	7,559,660	507,790	173,919	136,043
Estimated product of small mines	495,654	15,539	312,607	263,416	130,823	1,303,950	52,134	540	90		

[1] Includes allowance made for iron in ore, $73,941; quicksilver saved in reworking old tailings, $8,906; realized for old tailings whose contents could not be ascertained, $118,114; platinum, $198; osmiridium, $50.

Gold and silver as by-products of other ores.—The product of gold and silver mines does not include the precious metal contents of copper and iron ores. The refined product which is placed on the market includes, on the other hand, the precious metal contents of all ores, regardless of their source of production. In order to make the mining product comparable with the refined product the following table is presented, in which the gold and silver contents of all ores, as well as of placer bullion, are shown:

TABLE 38.—*Gold and silver contents of the product of all mines: 1902.*[1]

SOURCE OF PRODUCTION.	GOLD.	SILVER.
	Fine ounces.	Fine ounces.
Total	3,242,039	55,819,946
Gold and silver ores and placer bullion	3,149,128	42,746,064
Copper ores	92,911	11,452,280
Iron ores		1,621,602

[1] Not including Alaska.

The gold and silver contents of copper ores shown in the preceding table are included in the value reported elsewhere for the product of copper mines, and the silver contents of iron ores are included in the value reported for iron ores.

The argentiferous iron ores exemplify the difficulties attending every classification. Such of these as contain high values in silver, which permit of their working for that metal, were classed as silver ores. With most of these ores, however, their chief value lies in the fluxing qualities of their iron and manganese contents, yet the value received for them by the mine operator represents practically nothing but the value of their silver contents. With the exception of a small quantity, the disposition of which was not reported, all this ore was sold to the American Smelting and Refining Company, which settles for it in the following manner:

The producer of the ore is paid in full for its silver contents at the New York quotation; the percentages of iron and manganese are added together and the percentage of silica is deducted from the sum. If the difference is equal to 40 per cent of the weight of the ore no charge, as a rule, is made for smelting and freight. A bonus is paid for every "unit"—i. e., 20 pounds—over the 40 per cent basis, usually at 15 cents per "unit"—i. e., three-fourths cent per pound—or a deduction is made at the same rate for every unit short of the 40 per cent basis. The value of the product classed as iron ore is made up as follows:

	Value.
Silver (1,621,602 ounces)	$883,987
Allowance for other metals (copper, lead, iron, manganese)	66,716
Total gross value	950,703
Deductions	169,787
Value at mine	780,916

The average assay of silver was 7 ounces per ton, and the average gross value of the ore was $4.16 per ton; thus at the present price the value of the silver alone would not pay for the smelting of the ore but for the exceptionally low charge for smelting, viz, 74 cents per ton. The richness of the ore in iron and manganese is what makes such a low rate possible.

The following table is a summary of the mines producing argentiferous iron ore, not included in the statistics for gold and silver:

TABLE 39.—*Summary of mines producing argentiferous iron ore: 1902.*

Number of mines	17
Salaries	$36,580
Wages	$265,400
Contract work	$29,988
Work on share of product	$84,368
Rent and royalties	$85,474
Other miscellaneous expenses	$27,365
Cost of supplies and materials	$118,596
Ore sold, short tons	228,719
Gross value of bullion contents	$950,703
Average per ton	$4
Value of product at mine	$780,916

In the following table the gold and silver contents of all ores mined in 1902, including those in which the precious metals were merely by-products, are shown by states and territories:

TABLE 40.—*Gold and silver contents of all ores mined, by states and territories: 1902.*

[1] Estimate of the Director of the Mint.
[2] Includes Alabama, Arkansas, Maryland, Michigan, Tennessee, Texas, and Virginia.

Comparisons with the report of the Director of the Mint.—The Director of the Mint estimates annually, from the records of the United States mints and assay offices and from statements furnished by private refineries, the product of refined gold and silver from domestic ores. The methods followed in making these estimates are stated as follows:

In estimating the gold yield of the United States in any given year only that gold is looked upon as really produced that has been refined, made ready for the market, and the ascertained amount of domestic origin (which is comparatively insignificant) that has been exported to foreign countries for reduction.

It has been the custom of the Bureau of the Mint to make for every calendar year two independent calculations of the gold product of the country, and to take their mean as the closest approximation that can be had to the actual output of the mines. The first of these is based on the amount of gold put upon the market by private refineries during the year plus the fine gold contained in the unrefined bullion of domestic production deposited at the mints and assay offices of the United States plus the pure metal of domestic production contained in ores, copper matte, etc., exported to other countries for reduction. The second calculation is based on the known disposition made of the newly produced gold in any calendar year. Such gold is either deposited at the mints and assay offices of the United States, or exported from the United States in form of bullion, ores, or copper matte, or used in the industrial arts. If foreign gold bullion enters into any of the above items, its amount must, of course, be deducted.

The silver product of the United States in any given calendar year is estimated in precisely the same manner as the gold product, namely, by making two independent calculations of the same and taking their mean as the actual product.[1]

The variance between these two estimates is confined within narrow limits. The variances for 1902 are as follows: For gold, 61,029 ounces, or about 1.5 per cent of either calculation; for silver, 66,972 ounces, i. e., somewhat over one-tenth of 1 per cent.

[1] Report of the Director of the Mint on the Production of the Precious Metals, 1902, pages 13 and 14.

The precious metal contents of all ores mined in 1902, as ascertained by the census of mines and quarries in the continental United States, are collated in the following statement with the estimates of the Director of the Mint for the United States, exclusive of Alaska:

Precious metal contents, Bureau of the Census, and Mint returns: 1902.

	Product of mines reported by Census.	Refined product estimated by Director of the Mint.	DIFFERENCE.	
			Excess of mining product over refined product.	Excess of refined product over mining product.
Gold, fine ounces	3,242,039	3,466,270	.....	224,231
Silver, fine ounces	55,819,946	55,408,000	411,946	.....

It appears from the preceding statement that the output of silver reported to the Bureau of the Census slightly exceeds the estimate of the Director of the Mint, whereas the product of gold reported to the Bureau of the Census is 6 per cent below the estimate of the Director of the Mint. At the Eleventh Census the difference was as high as 13 per cent of the refined product. The decline of placer mining and of mining on a small scale generally, the settlement of the mining districts and the improvement of transportation facilities, together with the progress of statistical methods have all contributed to making the returns of the present census more complete than its predecessors. On the other hand, there can be no coincidence between mine returns and the refined product for the same year, inasmuch as a part of the mining product of one year is refined during the following year.

The Mint agents in their reports show the distribution of gold between placer and deep mines by states and territories. In the following table the reports of Mint agents are compared with the results of the Census:

TABLE 41.—*Comparative statement of the gold contents of the product mined, as reported to the Bureau of the Census, and by Mint officers and agents, by states and territories: 1902.*

STATE OR TERRITORY.	DEEP.		PLACER.	
	Census (fine ounces).	Mint officers and agents (fine ounces).	Census (fine ounces).	Mint officers and agents (fine ounces).

North Carolina	3,184	3,727	154	803
Oregon	63,632	77,086	25,394	11,798
South Carolina	6,749	7,257	.....	226
South Dakota	351,308	345,715	49	.....
Tennessee	8	.....	275	7
Utah	173,580	192,157	11	.....
Virginia	112	181	33	27
Washington	10,664	15,115	364	3,000
Wyoming	229	.....	.....	2,188

The sources of production as reported by Mint officers and agents are arranged under two heads only, "quartz" and placer. It is evident by comparison with the Director's estimate of the refined product that the designation "quartz" includes all deep mines.[1]

The difference between the two sources compared in the preceding statement amounts to 62,267 ounces for placers and 208,665 ounces for deep mines, in all 270,932 ounces. It must be borne in mind, however, that the quantities reported by Mint officers and agents exceed the Director's estimate of the gold product in the continental United States by 46,691 ounces.

The excess over the Census returns for placer mines is greatest in Colorado, where the Mint officers report 31,444 ounces, whereas the Census returns show only 3,172 ounces. It seems probable that Colorado is erroneously credited by the officers of the Denver mint with the placer bullion produced in adjoining states, but shipped to Denver to be deposited at the United States Mint. The placer product credited to Idaho by the United States Assay Office, at Boise, is 17,456 ounces in excess of the Census returns; on the other hand, however, the Census returns show an excess of 13,596 ounces over the Mint report for Oregon; it is very likely that the Oregon product found its way through bullion dealers to the Boise assay office.

The gold product of placer mines, as reported to the Bureau of the Census directly by producers, was valued at $4,204,995, which corresponds to the value of 203,757 fine ounces, as estimated above. In addition to this amount the unreported production of small mines was estimated by local men at $1,138,181, which corresponds to the value of 55,386 fine ounces. Most of the placer bullion ultimately finds its way to the mints and assay offices. The report of the Mint officers and agents should therefore be given preference over the estimates of other local men. The excess of the amount reported by Mint officers and agents over the aggregate output reported directly by producers to the Bureau of the Census, viz, 123,903 ounces, with a coining value of $2,561,075, represents the product of small mines.

The excess of the gold product of deep mines as reported by Mint agents over the Census returns is greatest in Arizona and Nevada, namely, in Arizona, 68,562 ounces, which is equal to 52.5 per cent of the Census returns, and in Nevada 58,386 ounces—i. e., 68 per cent of the Census returns.

The following comparative table shows the distribution of the silver production by states, as ascertained by the census of mines and quarries and as estimated by the Director of the Mint. The quantities reported by Mint agents are shown in a parallel column.

[1] Report of the Director of the Mint on the Production of the Precious Metals, 1902, page 16.

TABLE 42.—*Comparative statement of the silver contents of the product mined, as reported to the Bureau of the Census, and the product of silver refineries, as estimated by the Director of the Mint, by states and territories: 1902.*

[1] Estimate of the Director of the Mint.
[2] Includes Alabama, Maryland, Michigan, Tennessee, and Virginia.

Table 42 shows that while the Census returns for the United States, as a whole, substantially agree with the estimate of the Director of the Mint, there is a wide variance between the results for some of the states. The estimate of the Director of the Mint is 1,239,758 ounces, or 17 per cent short of the product ascertained by the Census for Idaho. On the other hand, the Census returns for Arizona are 1,386,175 ounces, or 45.5 per cent of the estimate of the Director of the Mint. Considering that the Census returns for other states, as well as the total for the United States, are in substantial harmony with the Mint estimates, it is not probable that the canvass of mines in Arizona by Census agents should have failed to reach 45.5 per cent of the silver product of that territory. Were it so, the difference for Arizona would have to be added to the Census total for the United States, in which case the estimate of the Director of the Mint would be 1,798,121 ounces below the total production of the United States. The Mint estimate of the total production for the United States, however, is more likely to be approximately accurate than its apportionment among the several states and territories, wherein the estimates of the Bureau of the Mint often widely disagree with the reports of its agents.

With special reference to Arizona, it is further possible that the excess of the Mint estimates over Census returns, both for the gold and the silver product, represents to some extent the product of Mexican mines brought over the border and sold in the United States.[1]

The Census returns for the silver product of Nevada slightly exceed the estimate of the Director of the Mint. Inasmuch as the silver product of Nevada usually occurs in association with gold, it would seem that the canvass of gold and silver mines must have been fairly complete. It is therefore difficult to account for the wide divergence between the Census returns and the Mint estimate of the gold product of the state. The vastness of the area to be covered and the sparseness of the population may to some extent have affected the Census returns; yet, considering that the variance between the Census returns and Mint estimates for other states is confined within comparatively narrow limits, it seems probable that Nevada has been credited by the Bureau of the Mint and its agents with much of the gold bullion brought from other states to the Carson City assay office.

Placer bullion usually carries silver; the quantity of silver, however, is in most cases too small to be figured in the value of the product. There were only 40 placer mines which reported separately the value of silver, amounting in all to $2,235. The reports of Mint agents, which are summarized in the statement below, place the coining value of silver at $12,752, corresponding to a commercial value of $5,129, at 52 cents per fine ounce.

The amount reported by Mint agents does not include the states of Colorado, Idaho, and Nevada. With the addition of the amount reported to the Bureau of the Census from these 3 states—viz, $1,444—the total value of the silver recovered as a by-product of placer mining amounts to $6,573. The difference between the Census returns and the Mint agents' estimates amounts to $4,338, which does not materially add to the silver production or reduce the gold production of the United States.

Gold and silver contents of placer bullion, as reported by Mint agents: 1902.[1]

	FINE OUNCES.		VALUE.		
				Silver.	
	Gold.	Silver.	Gold.	Commercial.	Coining.
United States	321,410	9,863	$6,643,985	$5,129	$12,752

[1] Figures taken from the Report of the Director of the Mint on the Production of the Precious Metals for the Calendar Year 1902, pages 86, 144, 145, 184, 187, and 212. Where only coining values were reported, fine ounces have been computed from such at a rate for gold of $20.67+ and for silver of $1.29. Commercial values have been figured at a rate of $0.52 per fine ounce.
[2] Includes Alabama, Georgia, Maryland, North Carolina, South Carolina, Tennessee, and Virginia.
[3] Includes Arizona, Arkansas, Colorado, Idaho, Nevada, New Mexico, South Dakota, Utah, and Wyoming.
[4] Not reported; included with gold.

Comparison with smelter returns.—Argentiferous lead and copper ores are reduced by smelting. There were only 3 lead smelters combined with silver-lead mines and constructed for the treatment of their own ores. Their total product for 1902 was equal to 137,002 ounces of silver and 1,884,591 pounds of lead, which was but a fraction of 1 per cent of the total product of silver-lead

[1] Report of the Director of the Mint on the Production of the Precious Metals, 1899, page 83.

mines. The product of these smelters was shipped to eastern refineries. The bulk of the silver and lead produced reached the smelters and refineries either in crude state or after only a preliminary milling treatment. As shown further in Table 43, the former contained 26,270,578 ounces of silver and the latter 16,207,767 ounces, exclusive of 267,119 ounces which were produced by small mines and could not be classified. According to reports received by the Bureau of the Census from smelters and refineries, the production of refined silver in the United States in 1902 was made up as follows:

	Fine ounces.
Produced by lead smelters and refineries	78,896,284
Produced by copper smelters and refineries	9,781,532
	88,677,816
Less contents of foreign ores reported	28,926,235
Total	59,751,581

The silver contents of foreign lead ores smelted on the Pacific coast were not reported, but the bullion product of those smelters is included in the above total. The ores imported through San Francisco, Cal., and Puget Sound, Wash., were valued at $2,519,289.[1] Figured at the rate of 52 cents per ounce of silver, they contained 4,844,786 ounces, which leaves 54,906,795 ounces of domestic silver. The total reported by private smelters and refineries to the Director of the Mint was 55,087,074 ounces.[2] Thus in all about 55,000,000 ounces of silver were produced by private smelters and refineries, of which over 44,000,000 ounces were produced from domestic ores by lead smelters and refineries. The last quantity covers the contents of all silver bearing ores, which shows the close interdependence between silver mining and lead smelting. The total silver product of 1902 was accordingly distributed by character of ore, as follows:

	Value.	Per cent.
Total value	$28,448,004	100.0
From gold and silver ores and placer bullion	[1]6,062,979	21.3
From argentiferous lead ores	15,385,872	54.1
From argentiferous iron ores	883,987	3.1
From copper ores	6,115,166	21.5

[1] Includes product of old dumps and tailings.

The total lead contents of argentiferous ores mined in 1902, including copper ores, amounted to 411,590,504 pounds. The refined lead product reported to the Bureau of the Census by lead smelters and refineries was 475,588,419 pounds, which included the production of foreign ores smelted on the Pacific coast and not segregated in the reports from smelters. The imports of lead in ore and base bullion at Puget Sound and San Francisco were reported as 27,969,934 pounds,[3] which must be deducted from the total reported by the smelters; this leaves 447,618,485 pounds of lead.

A portion of this quantity was produced from non-argentiferous lead; the United States Geological Survey estimates the quantity of soft lead refined by desilverizers at 5,395 tons, which leaves 436,828,485 pounds of argentiferous lead. The excess over the contents of ores mined equals 25,237,981 pounds, or 12,619 short tons. During 1902 the stock of domestic lead was reduced by 42,138 tons;[4] it is probable that the excess of the smelter returns represents the product of ores mined during the previous year. The United States Geological Survey estimates the yield of lead from argentiferous ores for 1902 at 195,571 tons.[5] This is 5 per cent short of the product reported by mine operators; the difference is easily accounted for by losses in smelting.

SHIPPING AND MILLING ORES.

The product after leaving the mine is treated either at a mill connected with the mine or at a custom mill in the vicinity; or it is merely concentrated at the mine and the dressed ore shipped to a smelter; or it is shipped in the crude state. Table 43 shows the tonnage, bullion contents, and gross value, total and per ton, of all ore sold and treated, classified according to the method of handling the same. No information of this character being available for certain small operators, from whom no individual reports were received, their estimated product is not included in Table 43.

The preceding table brings out the economic reasons governing the method of handling the ore. Where there was a mill at the mine the average value of the ore was about $7 per ton; where there was no mill at the mine the average value was $22. In the absence of a mill at the mine only ore of a higher grade was mined. On the other hand, where the ore could be reduced at the mine, low-grade ore was advantageously mined and treated. Even where there was a mill at the mine a portion of the ore was shipped to smelters. The value of such ore in 1902 averaged about $30 per ton, whereas the average grade of the ore treated at the mine was $6 per ton. Where there was no mill belonging to the mine the bulk of the ore was shipped, the value of the average grade of shipping ore being $23 per ton. In some districts the proximity of custom mills permitted the treatment of ores averaging about $17 per ton.

Another consideration which determines the method of handling the ore was the nature of its metallic contents. Ore shipped in crude state from mines without mill connection contained considerable values in silver, viz, $9,614,445, averaging 15 ounces per ton, whereas ores treated at neighboring custom mills were valued chiefly for their gold contents, silver averaging only 2 ounces per ton. Lead was also an important element in shipping ores, averaging 3.22 per cent of the ore, whereas in milling ores it was only a fraction of 1 per cent.

At mines with mill connection the value of the ores treated was nearly all in their gold contents, silver averaging 2 ounces per ton and lead only about 1.62 per cent. The ores shipped contained a greater value in silver than in gold, the average tenor in silver being 32 ounces per ton. The lead contents were also valuable, averaging 12.48 per cent of the crude ore. In such cases the ores were sorted before treatment; ore rich in silver and lead was shipped to smelters, the rest being treated at the mine.

A portion of the ore treated at the mills was merely concentrated preparatory to shipping. This was notably the case with ores rich in lead. The product of the mills contained 259,346,816 pounds of lead, which had to be extracted by smelting.

The total quantity of ore concentrated was, according to reports, 1,820,589 tons; but much more was probably concentrated, as the reports on this subject are incomplete. All this ore was concentrated at plants belonging to the mines. Only 38,376 tons were concentrated for outsiders, they being producers whose mines were located in the neighborhood of concentrating plants.

Concentration of ores before shipping is one of the

modern devices for the economical handling of ores. The quantity of concentrates produced was 206,330 tons; the quantity of crude ore treated to produce these concentrates was 1,820,589 tons, as stated; the average degree of concentration was accordingly 1 ton of concentrates to 9 tons of crude ore. This reduces the bulk of the ore to be shipped to one-ninth of its original weight; a large saving is thus effected in freight and treatment charges.

The prices which were paid for the metallic contents of the mining product varied in accordance with the condition in which it was marketed. Gold bullion, produced by amalgamating, cyaniding, and chlorination works connected with mines, sold at $20.44 per fine ounce; when the ore was reduced at custom mills, gold brought on an average $20.26 per ounce. Gold in ore brought from $19.21 to $19.99 per ounce. Silver was figured at 50 cents per ounce; a portion brought only 49 cents per ounce. Lead was disposed of at an average of 3 cents per fine pound; when sold as concentrates it averaged 3.2 cents per pound, while in the crude state it brought from five-tenths to 1 cent less. Copper brought from 5 to 8 cents per pound.

Charges for treatment and freight.—Charges for treatment and freight are governing factors in the working of mines. They are materially reduced when the ore is treated at the mine or concentrated. The total charges for treatment and freight reported from mines without a mill connection amounted to $11,050,789, of which $5,020,233 was treatment charges, $2,021,828 freight, and $4,008,728 could not be segregated, the charges and freight not being entered separately on the books of the operators. The total amount of treatment and freight charges reported from mines with mill connection was $10,277,686, of which $3,697,138 was treatment charges, $2,341,765 freight, and $4,238,783 could not be segregated.

The following table shows the treatment charges and freight, classified according to the method of handling the ore:

TABLE 44.—*Treatment charges and freight on the product of mines and mills: 1902.*

	Tons.	Gross value.	Treatment charges, including freight.	Average per ton.	Value at mine.
Total	9,788,124	$93,254,240	$21,328,475	$2.18	$71,925,765
Mines and mills, ores sold and treated	8,232,753	59,027,379	10,277,686	1.25	48,749,693
Mines without mill connection	1,555,371	34,226,861	11,050,789	7.10	23,176,072
Shipping ore	1,304,503	30,008,645	9,865,405	7.56	20,143,240
Milling ore	212,492	3,656,007	1,039,533	4.89	2,616,474
Concentrated ore	38,376	562,209	145,851	3.80	416,358

The greater part of the treatment and freight charges on the product of mills consisted of deductions on concentrates and on 253,847 tons of ore shipped in crude state (see Table 43). The refining charges on bullion may be estimated at 1 per cent of the value of the gold contents and at 4 cents per ounce of silver, which is the highest rate charged by the United States mints and assay offices. This rate makes a total of $369,246 on gold and $892,751 on silver—in all, $1,261,997, or, in round figures, about $1,200,000. This leaves somewhat over $9,000,000 for treatment and for freight on concentrates and crude ore.

The amount of freight varied for the several states and within the same state materially, according to the location of the mine. The treatment and freight charges set the limit to the working of certain grades of ore. Table 45 shows, by states and territories, the total tonnage of ores treated at outside reduction works, the total treatment charges, including freight, and the average per ton, and the highest and lowest freight rate per ton. The freight charges indicate the distances of the mines from railroad connections.

TABLE 45.—*Tonnage treated at outside works, treatment charges, and freight, by states and territories: 1902.*

STATE OR TERRITORY.	Total tons treated at outside works.	TREATMENT CHARGES, INCLUDING FREIGHT.		FREIGHT PER TON.			
		Total.	Average per ton.	Shipping ores.		Milling ores.	
				Highest.	Lowest.	Highest.	Lowest.

Utah	219,817	2,822,665	12.84	23.70	0.70	.....	.....
Washington	8,869	82,275	9.28	10.00	1.00	.....	.....
All other states[1]	22,374	121,191	5.42	.....	.....	.....	.....

[1] Includes mines located in Alabama, Arkansas, Georgia, North Carolina, South Carolina, Texas, Virginia, and Wyoming.

The freight rates were higher on shipping ores than on milling ores; the highest freight from the mine to the mill, $18 per ton, was paid in New Mexico; the highest freight from the mine to the smelter, $50 per ton, was paid in Arizona.

Grade of ore.—In Table 46 the gold and silver contents of all ores mined in 1902, wherein the precious metals were the chief item of value, are classified by the grade of ore. There were a number of cases which did not lend themselves to such a classification. In many mines the ore is sorted, first-class ore being shipped and second-class ore being treated at the mine. Census schedules did not call for a separate statement for each class of ore, and an average for all grades would fail for the purpose of this classification. However, as eight-ninths of the total gold product of deep mines and four-fifths of the total silver product have been classified, the table answers the purpose.

TABLE 46.—GOLD AND SILVER VALUES CONTAINED IN THE PRODUCT OF PRECIOUS METAL MINES, CLASSIFIED BY GRADE OF ORE, BY STATES AND TERRITORIES: 1902.

[1] Includes mines located in Alabama, Arkansas, Georgia, Idaho, New Mexico, North Carolina, Oregon, South Carolina, Virginia, Washington, and Wyoming.
[2] Includes mines located in Alabama, Arizona, California, Georgia, Idaho, New Mexico, North Carolina, Oregon, South Carolina, South Dakota, Texas, Virginia, and Washington.

It appears from the preceding table that little gold was produced in 1902 from ores worth over $50 per ton. About two-fifths of all gold produced was won from low-grade ores worth less than $10 per ton, and about the same share was obtained from ores worth $20 or over.

Considering the three principal gold producing states, Colorado, California, and South Dakota, and taking $20 per ton as the dividing line between high-grade ores and average or low-grade ores, it appears that in Colorado high-grade ores predominate, whereas in California and South Dakota the product was chiefly won from low-grade ores. In South Dakota practically all gold was derived from ores worth less than $10 per ton. Of the smaller gold producers, Utah also treated mostly low-grade ores.

Silver was likewise won mostly from ores averaging less than $20 per ton, but the lowest grade of ore, averaging less than $10 per ton, was not as conspicuous as in gold mining. A comparative study of Tables 45 and 46 will show the extent to which the distance of the mine from reduction works affects the grade of ore treated. In Arizona the highest cost of freight for shipping ore was $50 per ton. Very little gold, however, was produced from ores which could bear such a freight rate. In California the highest freight rate on shipping ores was $36 per ton, while two-thirds of all gold was derived from ores worth less than $10 per ton, and less than one-sixth was produced from ores worth from $20 to $50 and over. In South Dakota the highest freight rate on shipping ore was $15 per ton, but the bulk of the ore was worth less than $10 per ton, and the quantity of high-grade ore, which could bear the highest freight rate, was insignificant.

An examination of the average treatment charges, inclusive of freight, will show what portion of the gold and silver ores produced in each state must be treated at or near the mine and what portion can be shipped to distant works. Taking the United States as a whole, it appears that two-fifths of all gold and one-fourth of all silver are recovered from ores worth less than $10 per ton, which could hardly bear the average transportation charges of $7.39 per ton and can therefore be economically treated only at or near the mine. On the other hand, about two-fifths of all gold and silver are won from ores worth over $20 per ton, which could be profitably shipped to distant works for treatment.

The following comparative table shows the average grades of gold and silver ore mined in 1880 and 1902. The Tenth Census took no cognizance of the base metallic contents of gold and silver ores. To make the data of both censuses comparable the gold and silver contents only are considered in the table which follows:

TABLE 47.—TONS OF ORE TREATED, GOLD AND SILVER CONTENTS, TOTAL AND AVERAGE PER TON, BY STATES AND TERRITORIES: 1902 AND 1880.

[1] Includes Alabama, Arkansas, Georgia, Maryland, North Carolina, South Carolina, Tennessee, Texas, Virginia, Washington, Wyoming, Maine, New Hampshire, and Michigan.
[2] The commercial value of an ounce of silver for the census year 1880 was obtained by taking the average between the prices for 1879 and 1880, which is $1.134.
[3] In 1880 formed part of the territory of Dakota.

As appears from Table 47, in all states and territories, except Oregon, the grade of ore has considerably decreased, while at the same time the quantity of ore mined and the total gold and silver values show everywhere a remarkable increase. This fact furnishes unmistakable evidence of the progress of gold and silver mining since the Tenth Census. The development of transportation facilities and improvement of mining methods and reduction processes have enabled the mine operators to handle large masses of low-grade ore which could not have been profitably mined two decades ago.

Classification of mines by metals produced.—In Table 48 all deep mines are classified into two groups—(1) gold and silver mines and (2) argentiferous lead mines. The ore mined from the former is valued chiefly for its gold contents, though it carries considerable values in silver and small quantities of other metals. The mines of the latter class yield lead ores rich in silver and associated with gold and other metals.

The total gold contents of the ores of both classes were valued at $57,829,542, of which $5,734,677, or about one-tenth, was carried by argentiferous lead ores and $52,094,865 by gold and silver ores. The latter can again be divided into two portions; about one-half, valued at $26,898,810, carried considerable values in silver, the rest, valued at $25,136,100, was produced from mines which reported no value for silver. It is probable that in many cases this gold was likewise associated with silver, but the percentage of silver saved was too small to be of commercial value.

The silver-lead mines include also those which reported no values other than those for silver. The total product of such mines was valued at $430,281. It is probable, however, that some of this silver was associated with lead, but the percentage of the latter was below the 5 per cent limit paid for by the smelters.

The value of the product shown in Table 48 is only that of the ore actually sold or treated. Ore mined but not sold or treated is not taken into consideration for the following reason: Gold and silver ores are mostly reduced at mills connected with the mines. It will be remembered that in such cases the value of the increase or decrease of the stock of ore was not estimated. Argentiferous lead ores, on the contrary, are

all shipped to smelters, so that the value of the increase or decrease of the stock was oftener estimated for this class of ore than for gold and silver ores. In order to avoid artificial disproportion in the results obtained, the total value of the product at the mine includes only the value of the ore sold or treated and the amount received from custom work, less the cost of purchased materials.

TABLE 48.—*Summary of deep mines, classified by metals produced: 1902.*

	Total.	Gold and silver.	Argentiferous lead.

Average per mine	$334,038	$300,529	$416,078

[1] Does not include 2 mills run on old dumps and tailings.

DEEP MINES.

Mines with and without reduction works.—The majority of deep mines had no reduction works to treat their ores; about one-third of the total number were equipped with reduction works. The latter, however, contributed about two-thirds of the product of gold and silver mines. The average production of a mine which had no mill was $18,178, whereas the average for the 585 mines equipped with reduction works was $86,381. The average grade of ore treated by the former was worth $22, whereas the latter treated low-grade ore worth less than $10 per ton, viz, 316 mills treated ore averaging $8.65 per ton and 269 treated ore averaging $5.43 per ton. About one-half of the mines connected with mills furnished separate reports for the mine and the mill. A number of operators, however, kept only one account for both mine and mill, and so reported them.

The following table is a comparative summary of mines with and without reduction works; mines and mills for which distinct reports were furnished are presented under a separate head:

TABLE 50.—*Deep mines with and without mill connection: 1902.*

[1] Does not include 48 arrastras, nor 27 mines whose product was reduced in hand mortars.
[2] Includes ore treated at custom mills.
[3] Includes $254,797 charged by reduction works against their own mines and credited by the latter to their reduction works.

Arrastras.—The primitive Mexican arrastra, in its old-fashioned form or somewhat modernized, has survived in a few small mines. The total number of mines reporting arrastras was 47, viz, 36 in California, 6 in Oregon, 3 in Idaho, 1 in Arizona, and 1 in New Mexico. At 23 no hired labor was employed.

The total value of the product of all such mines was $77,818, the average per mine being $1,655. The average tonnage treated was 75 tons per mine. A summary of mines with arrastras is presented in the following table:

TABLE 51.—*Summary for arrastras: 1902.*

Number of mines	47
Number of owners working	57
Salaries	$250
Wages	$16,388
Work on share of product	$2,170
Miscellaneous expenses	$956
Cost of supplies and materials	$5,228
Ore treated, short tons	3,502
Value of bullion contents:	
Gold	$78,298
Silver	$1,086
Total gross value	$79,384
Average per ton	$22
Treatment charges and freight	$1,566
Value at mine	$77,818
Average per mine	$1,655

Ore treated by hand.—Even the crudest form of treatment of ore in a hand mortar was found in a few cases. As a survival of archaic methods of production these mines well deserve notice. The 28 mines at which the ore was treated in such manner were distributed among the following states: California, 19; Oregon, 8; and Maryland, 1. The total output of these mines aggregated $48,280, averaging $1,724 per mine. There were 36 owners working in the mines, only 6 of which were operated with hired labor. The average quantity thus treated was less than 9 tons per mine, but the average value per ton was $200. There was evidently no regular production, but in every case a rich strike had been found by men of small means, who had no other facilities for treating their ore. A summary of these mines is presented in the following table:

TABLE 52.—*Summary for mines where the ore was treated in hand mortars: 1902.*

Number of mines	28
Number of owners working	36
Salaries	$985
Wages	$8,367
Miscellaneous expenses	$1,728
Cost of supplies and materials	$3,519
Ore treated, short tons	242
Bullion contents—	
Quantity—	
Gold, fine ounces	2,399
Silver, fine ounces	23

Gold	$48,424
Silver	$12
Total gross value	$48,436
Average per ton	$200
Value of product at mine	$48,280
Average per mine	$1,724

Custom mills.—The following is a summary for mills which were operated independently of mines on purchased or custom materials. It comprises 24 mills in Colorado, 10 in California, 9 in Nevada, 4 in Idaho, 3 in New Mexico, and 1 each in Arizona, Montana, Oregon, South Dakota, and Utah.

TABLE 53.—*Summary for custom mills: 1902.*

Number of mills	55
Salaried officials, clerks, etc.:	
Number	65
Salaries	$141,126
Wage-earners:	
Average number	684
Wages	$578,101
Miscellaneous expenses	$254,980
Cost of supplies and materials	$723,807
Cost of purchased ore	$5,951,048
Freight on purchased ore	$411,504
Ore treated, short tons:	
Total	533,730
Purchased ore	352,316
Custom ore	181,414
Value of bullion contents of purchased ore:	
Gold	$8,332,350
Silver	$102,029
Total gross value	$8,434,379
Average per ton	$24
Treatment charges and freight	$23,525
Value of product at mill	$8,410,854
Amount received for custom work	$289,205
Total value at mill	$8,700,059
Average per mill	$158,183

Among the 55 mills comprised in the preceding summary there were 7 which were operated without hired labor; the number of owners personally working in their mills was 15. The time in operation was reported by 45 custom mills; the data furnished by them are included in Tables 17, 18, and 20. Of this number, 12 ran more than three hundred days during the year and 7 from two hundred and seventy-one to three hundred days; these 19 mills may be taken as representing all that were in continuous operation throughout the year, except on holidays and when stoppages were necessary for repairs, etc. Of the other 26 mills, operated only part of the year, 11 ran from ninety-one to two hundred and seventy days and 15, ninety days or less; that is, only during the busiest season.

The majority, when working, ran more than one shift, viz: 25 ran two shifts and 7 three shifts, while 13 ran only one shift. When two or three shifts were run the mill was operated uninterruptedly during twenty-four hours, making either twelve or eight hours per shift, except in 2 mills, where two shifts of eight hours each were run. Of the 13 mills running only one shift 7 were working twelve hours per day, 5 ten hours, and 1 eight hours. On the whole, twelve hours per shift was the working time in 30 mills, ten hours in 5 mills, and eight hours in 10 mills.

The total capacity of all custom mills per twenty-four hours was 2,892 tons. Two mills which treated during the year 350 tons failed to report their daily capacity. The total tonnage treated by all mills reporting their capacity was 533,380 tons. It required accordingly 184 days of twenty-four hours to handle that quantity of ore. This fact shows that the mines provided a sufficient supply of ore to keep the custom mills in continuous operation every day in the year with one working shift of twelve hours per day, including Sundays and holidays.

The total value at mill in Table 53 is $8,700,059. In computing the total value of the product shown in Table 35 for all mines and mills in the United States, the value of purchased materials was deducted in order to prevent duplications. The mills handled practically only gold ore of a high grade, averaging $24 per ton. About two-thirds of the ore treated at custom mills was purchased by them, and only about one-third was treated for customers at a stipulated rate per ton, the product being returned to the customers. Some custom work was occasionally done at mills connected with mines; it was only as an exception, however, that ore was purchased at such mills. In the statement which follows, the quantities of ore purchased and treated for a stipulated compensation per ton are summarized for all mills, those connected with mines as well as custom mills:

Tons of ore bought and treated for a stipulated compensation: 1902.

CHARACTER OF REDUCTION WORKS.	Purchased ore.	Custom work.
Total	353,283	243,644
Custom mill	352,316	181,414
Connected with mine	967	62,230

The reports from mines whose ore was treated at custom mills show 212,492 tons reduced to bullion and 38,376 tons concentrated and shipped to smelters for reduction; in all, 250,868 tons. The mine operators reported 7,224 tons, or 2.9 per cent more than was traced to mills.

There are many reasons why the returns from establishments representing successive stages of production can not exactly coincide. Among other things, the census was taken in the spring and summer of 1903 for the calendar year 1902. Some of the mills which had been in operation a few months in the early part of the year 1902 were idle or dismantled at the time the census was taken and their owners could not be located. Still, the preceding comparison shows that the omission was not material.

Mills in 1902 and 1880.—The following statement presents the comparative data relating to mills for 1902 and 1880. Making allowance for the incompleteness of the Tenth Census, the statement shows a remarkable increase both in the number of reduction works and the total quantity of ore treated by them. The average turnover per mill has also increased.

Production of mills: 1902 and 1880.

YEAR.	Number of mills.	TONS TREATED. Total.	Average per mine.
1902	640	8,444,967	13,195
1880	169	1,467,479	8,683

METHODS OF TREATING THE ORE.

Of the 585 reduction works connected with deep mines, 456 were stamp mills, in which the ore was reduced by amalgamation; 83 were equipped with cyaniding plants, 16 with chlorination plants, and 301 with concentrators. Of the 55 custom mills, 46 were stamp and amalgamation mills, 10 were equipped with cyaniding, 5 with chlorination, and 21 with concentrating plants. There were, moreover, 27 mills which were run mainly on old mine dumps and mill tailings, though occasionally doing custom work. Of these, 16 were cyaniding works, 4 were stamp mills, and 7 were concentrating plants.

A difference in methods of transacting business among the various classes of custom mills deserves to be noted. Where the ore is treated by amalgamation, with or without concentration of the tailings, the mill operator, as a rule, does the work for the customer's account for a stated compensation and returns the product to the mine owner. At chlorination and cyaniding works, on the contrary, the ore is bought outright.

The relative place held by each class of mills in the gold and silver mining industry is shown by a comparison of the gross values of the ores treated by them. It should be noted that some cyaniding and chlorination works were also equipped with stamp mills and concentrating plants where a portion of the ore was treated.

Method of treating ore, by classes of mills: 1902.[1]

CHARACTER OF PROCESS.	Total.	Mills connected with mines.	Custom mills.
Total	$58,070,917	$49,636,538	$8,434,379
Amalgamation	3,260,246	3,260,246	.....
Concentration	14,248,871	14,248,871	.....
Amalgamation and concentration	14,103,276	14,102,176	1,100
Cyaniding, alone or in combination with other processes	16,588,667	15,674,687	913,980
Chlorination, alone or in combination with other processes except cyaniding	9,869,857	2,350,558	7,519,299

[1] Exclusive of mills operating only on old dumps and tailings.

Amalgamation and concentration.—Table 54 is a summary for amalgamation mills and concentrating plants. Where the ore was treated only by amalgamation its chief value consisted in its gold contents, though considerable values in silver were also saved. The values shown for "other metals" were realized from the sale of the tailings. The average grade of ore treated was worth only $6 per ton. A small quantity of high-grade ore averaging $68 per ton was shipped in crude state.

Where the ore was merely concentrated its main value was in its base metal contents (practically all lead). The ore averaged in crude state for one group of mills $11 per ton, and for another $7, and had to be concentrated before it could be shipped. High-grade ore was sorted out before concentrating and shipped in crude state; such ore shipped from the same class of mills averaged $28 and $43 per ton, respectively.

Where amalgamation was supplemented by concentration the chief value was in gold. These mills from which complete reports were received showed some values for silver and base metals; where the accounts were not kept separately for the mine and mill the total value was reported as gold, though in all probability it included some silver and base metals.

There was also a marked difference in the volume of production according to the character of the process applied: The value of the average product per mine with stamp mill (amalgamation) was a little over $15,000; the average per mine with stamp mill and concentration plant was over $50,000, while mines in which the base metals predominated reported a much higher average production, valued at over $100,000.

The average production per custom mill represented its earnings for custom work. The operations of ordinary stamp mills were quite small, averaging $1,385 per mill. Where stamp mills were equipped with concentrating plants the operations were conducted on a somewhat larger scale, averaging $8,488 per mill. It must be borne in mind that these averages are not comparable with those for stamp mills connected with mines, since the value of the ore is not included in the former, as the custom mills bought no ore.

[1] Exclusive of custom ores.

[2] Ore from abandoned mine.

Chlorination plants.—There were in all 22 chlorination plants, of which 4 were combined with cyaniding plants and are included with the latter in a subsequent table. Of the remaining 18 only 7 treated their ores exclusively by chlorination; in all others the ore was first treated by amalgamation and the tailings were then treated by chlorination. In 10 mills the chlorination process was preceded by concentration.

The following table is a summary of all mines and mills with chlorination plants:

TABLE 55.—MINES AND MILLS, WITH CHLORINATION PLANTS: 1902.

[1] Includes $254,747, amount earned for treating 63,000 tons of ore which are included in ore sold, as treatment charges could not be segregated.

Cyaniding plants.—An exhaustive treatment of the cyaniding process will be found in a special chapter following this report. Table 56 is a summary for cyaniding mills of all descriptions, including those running on old dumps and tailings. The first five columns of the table relate to cyaniding plants connected with mines and the last column to custom mills. The former are classified according to methods of treatment, under the following heads: (1) cyanide only, (2) cyanide with crushing, (3) cyanide with amalgamation, (4) cyanide with chlorination, and (5) miscellaneous. The last column includes all mills whose expenses were not separately reported, as well as those combined with smelters, for which separate reports were furnished. The number of custom mills was too small to permit of the same classification without disclosing the identity of some individual plants.

Table 56 contains an item of $908,156, representing the value of ore shipped to other works; one portion of this amount, viz, $495,403, represents the value of ore treated at other works owned by the same operators; the quantity of this ore was not separately reported, and is therefore included in the total quantity. In computing the average value per ton it was therefore necessary to add this value in the total value of bullion contents mined and treated; the amount thus added being about 3 per cent of the true value, the error in the average can not exceed 15 cents per ton, which is immaterial, cents being disregarded in the averages.

Cyaniding plants were mostly connected with mines; very little cyaniding work was done by custom plants. The total quantity treated at the latter was only 145,730 tons, most of which was old mine and mill dumps, whereas the total quantity cyanided at plants connected with mines was 546,286 tons, not including ore treated at mines where cyaniding was combined with other processes.

The average grade of ore treated by cyaniding at the mine was worth $5 per ton; the average grade of ore treated at custom mills was higher, somewhat over $8, which is quite natural, as the ore had to bear the additional expense of transportation. The value of the ore treated at the mine where cyaniding was the only process, or combined with amalgamation, averaged $4 per ton; where it was combined with chlorination it was found possible to treat ore worth on the average about $3 per ton. In some cases the ore was sorted, ores of a higher grade or rich in silver being shipped, while low-grade ores were treated at the cyaniding plants. The following statement shows the bullion contents of ore sold in crude state:

Bullion contents of ore sold crude: 1902.

Tons sold	60,273
Bullion contents:	
Gold—	
Ounces	29,757
Value	$560,316

Pounds	40,000
Value	$4,000
Total gross value	$652,103
Average per ton	$11
Value at mine	$412,753

Reworking old dumps and tailings.—The development of transportation facilities and the introduction of improved processes of treatment have made it profitable to rework low-grade ores which in former years were left on the dump. The quantity of such ore treated is seldom figured as a separate item in mine accounts, and was reported to the Bureau of the Census in only a few cases. Still there were 27 custom mills operating principally on old dumps and tailings. A summary of the same is presented in the table below. Of these, 16 were cyaniding, 4 amalgamating, and 7 concentrating plants. At the last named the ore was merely concentrated and then shipped to other works for treatment. The plants were not large, employing on an average about one person on a salary and about four wage-earners. The ore and tailings treated by cyaniding averaged a little over $3 per ton.

Amount received for custom work	$28,359	$3,206	$25,153
Total value at mill	$389,404	$272,339	$117,065
Average per mill	$14,422	$17,021	$10,642

[1] Does not include custom ores.

PLACER MINES.

The following table presents comparative statistics of the production of placer mines in 1902 and 1880:

TABLE 58.—*Gold product of placer mines, by states and territories: 1902 and 1880.*

STATE OR TERRITORY.	1902	1880
	Fine ounces.	Fine ounces.
United States	535,697	580,766
Alaska	[1] 276,554	288
California	182,370	415,105
Colorado	3,172	4,922
Georgia	3,280	3,234
Idaho	17,091	42,553
Montana	19,289	56,256
Nevada	1,423	2,419
New Mexico	5,722	.....
North Carolina	154	227
Oregon	25,394	44,811
Washington	364	5,757
All other states and territories [2]	884	5,194

[1] Estimates of Mint officers and agents.
[2] Includes Alabama, Arizona, South Carolina, South Dakota, Tennessee, Virginia, Utah, and Washington.

The decline of placer mining in continental United States is apparent from the preceding table. While making an allowance for the incompleteness of the present Census returns for placer mines, it must be remembered that those of the Tenth Census were much more defective. About one-half of the total placer product came from Alaska. Of all other states and territories, New Mexico alone has developed some placer mining since the Tenth Census.

Methods of working.—The methods of working in use in placer mines were reported as follows: Hydraulicking, 469 mines; sluicing, 349; drifting, 112; dredging, 44; electric elevator, 1. The shares contributed by these methods to the production of placer mines are shown in the following statement:

Product of placers, classified by method used: 1902.

METHOD OF WORKING.	Value of product at mine.	Per cent.
Total	$5,327,726	100.0
Hydraulicking	1,618,169	30.4
Dredging	1,329,039	24.9
Other methods	1,242,337	23.3
Not stated	1,138,181	21.4

The following table is a summary for placer mines, classified by method of working:

TABLE 59.—*Summary for placer mines, by method of working: 1902.*

	Total.	Hydraulic.	Dredging.	All others.
Number of mines	975	469	44	462
Without hired labor	396	141	.....	255
With hired labor	579	328	44	207
Number of owners working	950	385	.....	565
Salaries	$324,418	$142,732	$106,747	$74,939
Wages	$1,818,758	$885,101	$321,272	$612,385
Contract work	$19,953	$10,907	$2,998	$6,048
Work on share of product	$76,749	$33,562	$3,600	$39,587
Royalties	$145,727	$45,840	$69,358	$30,529
Miscellaneous expenses, exclusive of royalties	$133,758	$59,749	$57,333	$16,676
Cost of supplies and materials	$790,986	$274,745	$345,329	$170,912
Value of product at mine	[1]$4,189,545	$1,618,169	$1,329,039	[1]$1,242,337
Average per mine	$4,295	$3,450	$30,205	$2,689
Mineral lands:				
Total acreage held	186,660	108,889	18,507	59,264
Owned, acres	167,366	99,196	14,857	53,313
Leased, acres	19,294	9,693	3,650	5,951

[1] Does not include an estimated product of $1,138,181 for a number of small mines for which no reports were received directly from operators.

Hydraulicking.—The 469 mines worked by the hydraulic method were located mainly in California, where there were 221 mines. Oregon had 137 mines, Idaho 72, Colorado and Montana 10 each, and Georgia 9. All other states combined reported only 10 mines. A summary for hydraulic mines is presented in the following table:

TABLE 60.—*Summary for hydraulic mines: 1902.*

	Total.	Productive.	Developing and producing.
Number of mines	469	[1] 397	72
Number of operators	469	397	72
Without hired labor	141	135	6
With hired labor	328	262	66
Number of owners working	385	364	21
Salaries	$142,732	$90,555	$52,177
Wages	$885,101	$647,866	$237,235
Contract work	$10,907	$2,770	$8,137
Work on share of product	$33,562	$33,562	.....
Rent and royalties:			
Water rents	$27,013	$22,794	$4,219
Land, plants, and tunnels	$17,617	$17,467	$150
Other rents and royalties	$1,210	$1,210	.....
Miscellaneous expenses, exclusive of rents and royalties	$59,749	$43,144	$16,605
Cost of supplies and materials	$274,745	$178,293	$96,452
Value of product at mine	$1,618,169	$1,521,562	$96,607
Average per mine	$3,450	$3,833	$1,342
Mineral lands:			
Total acreage held	108,889	80,776	28,113
Average acreage per mine	232	203	390
Owned, acres	99,196	72,348	26,848
Leased, acres	9,693	8,428	1,265

[1] Includes 1 mine for Virginia; no item shown.

About two-thirds of all mines worked by hydraulicking—viz, 307 out of 469—reported their average yield per cubic yard of gravel treated. The arithmetical mean of 260 answers for active producers was 34 cents per cubic yard, and the mean for 47 mines under development was 33 cents. The average returns are much higher than those reported at the Tenth Census, when in many mines the product was not above 10 cents per yard, and in some favorably situated workings a considerably lower rate of production was found profitable.[1] Apparently the débris legislation regulating the erection of dams for the protection of navigable waters and farming lands has added to the expense of hydraulic mining, and so permits of the working of a higher class of gravel only. This accounts for the decline of hydraulic mining, which is evidenced by the following comparative statement:

Summary for hydraulic mines: 1902 and 1870.

	1902	1870
Number of mines	469	362
Salaries	$142,732	(1)
Wages	$885,101	$906,559
Value of product at mine	$1,618,169	$2,508,531
Average per mine	$3,450	$6,930

[1] Not reported.

Placer mines combined with stamp mills.—Placer deposits are sometimes found in ancient river beds covered with a lava cap, in which case the cemented gravel is treated by crushing and amalgamation in stamp mills. Eight mines of this character were reported by the present census—7 in California and 1 in Georgia. A summary for the same follows next below:

TABLE 61.—*Summary for placer mines equipped with stamp mills: 1902.*

Number of operators	8
Salaried officials, clerks, etc.:	
Number	8
Salaries	$6,105
Wage-earners:	
Average number	67
Wages	$53,336
Contract work	$137
Work on share of product	$3,232
Miscellaneous expenses	$7,641
Cost of supplies and materials	$10,130
Value of gold at mine	$130,606
Amount received for custom work	$750
Total value of product	$131,356

Dredging.—This new method, which marks the latest technical progress in alluvial mining, deserves especial attention. The total product of gold dredged for the year 1902 was valued at $1,329,039, of which $846,421 was produced in California, $278,617 in Montana, $81,823 in Idaho, and $122,178 in Georgia and New Mexico. In 1901 the product of dredging in California was estimated at $471,762 and in 1900 at $200,000.[2]

Of the 44 mines operated by dredging, 8 were engaged mainly in developing, comparatively little gold being produced by them. These 8 mines comprised 4 in Idaho, 3 in California, and 1 in Georgia. The 36 productive mines were distributed as follows: Seventeen in California, 9 in Idaho, 5 in Montana, 3 in Georgia, and 2 in New Mexico.

There were 34 incorporated and 10 unincorporated companies. The incorporated companies were distributed by states as follows: Eighteen in California, 8 in Idaho, 5 in Montana, 2 in New Mexico, and 1 in Georgia. Of the 34 incorporated companies, 7 were reported in the development stage, and of the remaining 27 only 5 paid

[1] Tenth Census, Vol. XIII, Report on Precious Metals, page 200.

[2] Report of the Director of the Mint on the Production of the Precious Metals, 1901, page 91.

dividends in 1902, namely, 4 in California and 1 in New Mexico. The total dividends paid by these 5 companies amounted to $246,810, of which $4,760 was paid on $68,000 of preferred stock, averaging 7 per cent, and $242,050 on $1,104,000 of common stock issued, averaging 21.9 per cent. In addition to that, 1 company paid the sum of $7,680 as interest at the rate of 6 per cent on its outstanding bonds amounting to $128,000.

There was no gold dredging mine with a product of $250,000 or more. Classified by value of production reported, the 44 mines reported ranked as follows: Four with a product exceeding $100,000, and with a total of $582,598; 8 ranging between $50,000 and $100,000, with a total of $483,215; 10 ranging between $10,000 and $50,000, with a total of $199,754; 15 ranging between $1,000 and $10,000, with a total product of $59,275; 5 ranging between $500 and $1,000, and 2 producing less than $500, with a total product of $4,197. It appears from the preceding figures that four-fifths of the entire output was contributed by 12 companies, producing each between $50,000 and $250,000.

A summary for gold mines operated by dredges and the capitalization of all incorporated gold dredging companies are presented in the two tables following:

TABLE 62.—SUMMARY FOR GOLD MINES OPERATED BY DREDGES: 1902.

	Total.	Productive.	Developing and producing.	Unincorporated.	INCORPORATED.			
					Total.	Nondividend paying.

Montana	8,000	800,000	5,514	551,400		150	150,000	128	128,000	7,680	6.0
New Mexico											

The following power was used to operate the dredges: One hundred and nineteen electric motors with 4,295 horsepower owned, in addition to which 3,762 horsepower was rented from other electrical plants, making in all 8,057 horsepower; 68 steam engines with 2,385 horsepower, and 7 water wheels with 1,740 horsepower. Most of the electric power, viz, 99 motors with 3,375 horsepower, and 3,412 horsepower rented, was used in California. The power used to run dredges constituted three-fourths of the total power used in the placer mines.

The following statement shows the area of land owned and leased by gold dredging concerns; acreage was not reported for 11 mines:

Gold dredging mineral lands owned and leased, by states and territories: 1902.

	Number of mines.	ACREAGE, MINERAL LANDS.			
		Total.	Owned.	Held on lease.	Average per mine.
United States	33	18,507	14,857	3,650	561
California	18	6,596	6,396	200	366
Idaho	9	4,603	4,603	.....	511
Montana	4	4,050	3,600	450	1,012
New Mexico	2	3,258	258	3,000	1,629

The following statement shows the distribution of mineral lands among the 33 companies reporting on the subject of land tenure:

Mineral lands, classified by area held: 1902.

	Number of mines.	ACREAGE.	
		Total.	Per cent of total.
Total	33	18,507	100.0
20 acres or less	1	20	0.1
21 to 99	3	246	1.3
100 to 999	24	8,591	46.4
1,000 and over	5	9,650	52.2

It must be understood that the land ownership shown in the preceding statements represents as yet only the possibilities of gold dredging. The area actually treated during the year 1902, in so far as reported, aggregated only 214 acres, from which gold to the amount of $1,243,364 was produced. Fifteen companies, with a total product of $185,675, failed to report the total acreage treated. The average yield per acre, for mines reporting, was $5,870. Twenty-six mines, with an aggregate output of $978,508, reported their average yield per cubic yard of gravel treated. The arithmetical mean of their average returns was $0.26 per cubic yard. In computing the mean yield the cubic volume of ground treated was not considered, as it could seldom be accurately ascertained; yet the average yield reported, being the result of numerous tests made, is thought to deserve attention.

TENDENCY TOWARD CONCENTRATION.

Gold and silver mining is no exception to the general trend of modern industry toward production on a large scale. This is illustrated by the following five tables, which present a classification of all mines and mills by value of production. Table 64 comprises all mines and all mills combined with mines, showing separately placers, deep mines without mills, and deep mines with mills. Table 65 deals with custom mills only. Table 66 presents a similar classification of all mines and mills by states and territories. Table 67 presents the same classification for gold and silver and for argentiferous lead mines, and Table 68 presents the same classification for incorporated mines, dividend paying and nondividend paying mines being shown separately. Only productive mines are dealt with in the last table; mines designated as "developing and producing"—that is, those at which expenditures were in excess of receipts—are eliminated from the comparison. In order to avoid disclosing the identity of individual concerns it has been necessary in Tables 65, 66, and 68 to combine certain groups shown separately in Tables 64 and 67.

TABLE 64.—CLASSIFICATION OF MINES BY VALUE OF PRODUCT: 1902.

PRODUCTION OF GOLD AND SILVER IN THE UNITED STATES FROM 1889 TO 1902.

The statistics of the production of the mines are collected annually by Mint officers and agents from mine operators. The statistics of the production of refineries are collected by the Bureau of the Mint. The former, as a rule, show an excess over the latter, varying from 1 per cent to 11.4 per cent for gold and from one-tenth of 1 per cent to 11.3 per cent for silver. In 1890, however, the estimate of the Director of the Mint exceeded the total gold product reported by Mint agents by 2.9 per cent. The estimated production of silver refineries exceeded the product of the mines in 1891 by five-tenths of 1 per cent, in 1893 by 13.2 per cent, and in 1896 by 8.5 per cent. The estimated production of refined silver is equal to the total silver production of domestic refineries less the silver contents of foreign ores reduced in the United States. The fluctuations in imports of silver must inevitably affect the estimate of the refined product, thus creating a disproportion between the latter and the production of the mines in the United States for the same year.

The excess appearing from year to year in the production reported by mine operators, as compared with the product of refineries, is easily accounted for by the fact that the former is largely an estimate of the assay contents of all ore mined, regardless of the quantity of ore which will eventually be left on the dump after sorting, as being of too low a grade to pay for freight and reduction; nor are the losses in smelting always considered by the mine operator in estimating the assay contents of his ore.

The following table shows the gold and silver product of mines and refineries from 1889 to 1902, compiled from the annual reports of the Director of the Mint on the production of the precious metals:

TABLE 69.—PRODUCT OF MINES AND REFINERIES: 1889 TO 1902.

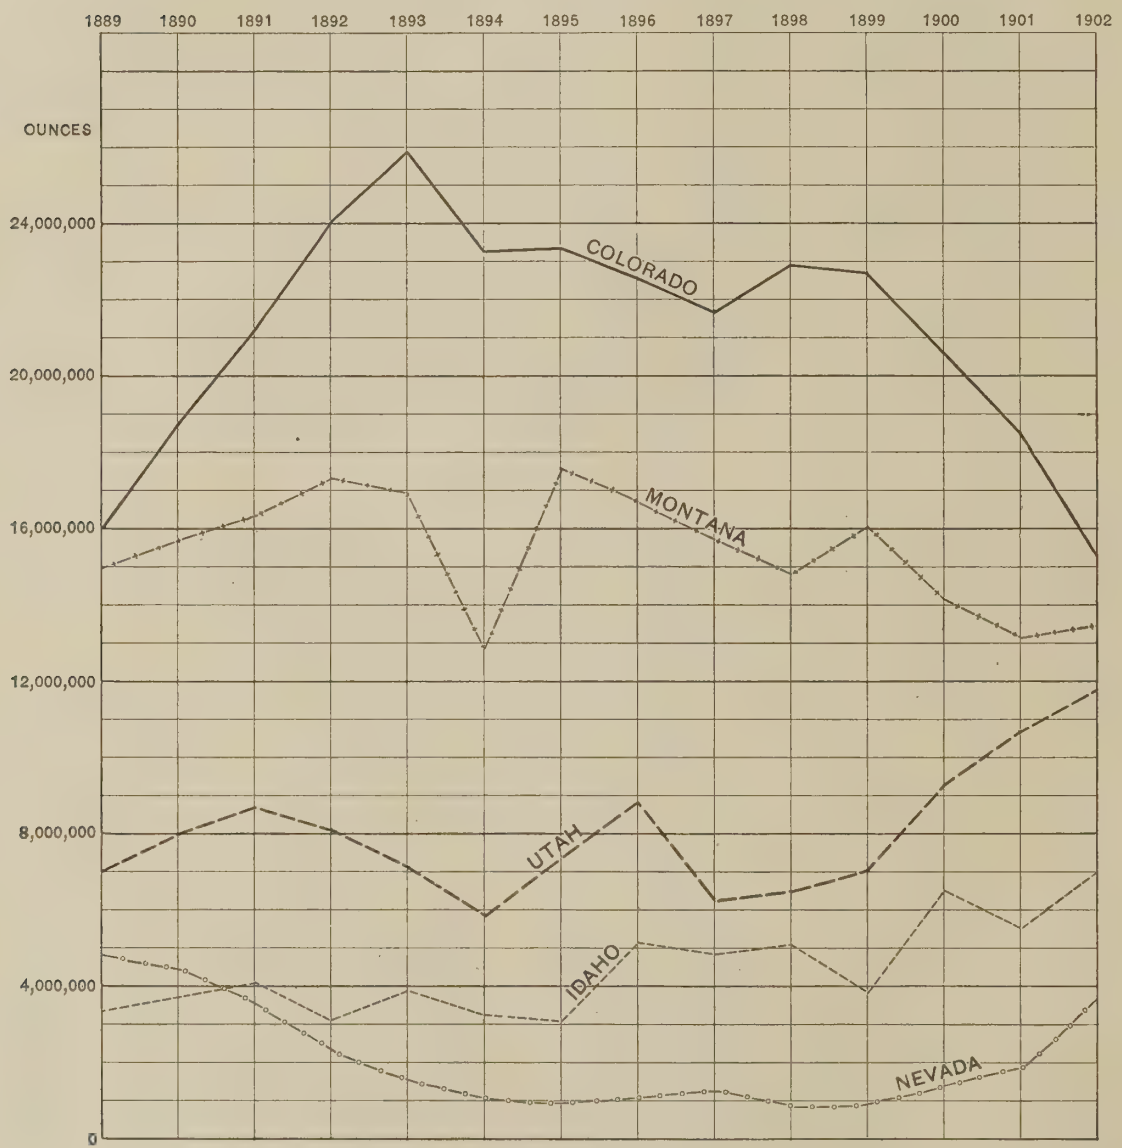
[3] Exclusive of 2,000 ounces reported for "other states" in the Report of the Director of the Mint, which was evidently a duplication.

REVIEW OF THE INDUSTRY BY STATES.

The development of the production of gold and silver in the several states and territories from 1889 to 1902 is illustrated by Diagrams I, II, III, and IV. Diagram I, based upon the estimates of the Director of the Mint, shows the growth of the gold production in the principal states and territories and the rank of each as a gold producer; the wide variance between the Mint estimates of the gold output by states and territories and the corresponding Census returns precludes the use of the latter for comparative purposes. The fluctuations of the silver production in the principal states during the same period are represented by Diagram II, prepared from the same source, except for the year 1902, for which Table 40 of the present report was used. Dia-

DIAGRAM II.—PRODUCTION OF SILVER FROM 1889 TO 1902 IN THE STATES REPORTING MORE THAN 2,500,000 OUNCES IN 1902.



grams III and IV, prepared from the same source as Diagram II, show the share contributed by each state and territory to the total production of gold and silver from year to year.

Colorado held in 1902 the first rank among the states and territories as a producer of both gold and silver. The Colorado ores contributed more than one-third of the gold and more than one-fourth of the silver contents of all ores mined in the United States. The second place among the gold producing states was held by California, which contributed over one-fifth of the gold product of the United States. Next after California came Alaska, with one-ninth of the total gold product and with more than one-half of the placer gold produced in the United States. South Dakota, Montana, Utah, Arizona, Oregon, Nevada, and Idaho followed in successive order. All other states and territories each produced less than $1,000,000 in gold.

The second rank as a silver producing state was held by Montana, which furnished nearly one-fourth of the silver contents of all ores. Nearly three-fourths of the silver was derived as a by-product of the smelting of copper ores, viz, 9,675,613 fine ounces out of a total of 13,441,950 ounces. Utah followed closely, with over one-fifth of the total output of silver. Idaho and Nevada came next. All other states and territories each produced less than $1,000,000 in silver.

Silver, as previously stated, was mostly recovered from argentiferous lead ores, where lead formed a valuable portion of the product. The first rank as a producer of argentiferous lead ores was held by Idaho. The combined silver and lead contents of all ores mined in that state were valued at $10,291,494. Utah followed next, with a total value of $8,261,095, and Colorado held the third rank, with $7,296,925. The production of argentiferous lead ores in other states was insignificant. The Colorado ores were the richest in silver, only one-fourth of the value of their bullion contents representing lead. The value of the bullion contents of Utah argentiferous lead ores was nearly two-thirds in silver and a little over one-third in lead. In Idaho, on the contrary, the ores were poor in silver, more than two-thirds of the value of their metallic contents being lead and less than one-third silver.

Taking the lead values alone, Idaho contributed $7,122,838; Utah, $2,873,740; Colorado, $1,827,993; and all other states $486,671. These values do not correspond to the quantities of lead, inasmuch as the price realized in Idaho averaged 3.4 cents per pound of fine lead contents, whereas in Utah it averaged 2.7 cents and in Colorado 2.25 cents per pound. The lead contents of Idaho ores were more than one-half of the total for all argentiferous lead ores mined in the United States. Utah contributed a little over one-fourth and Colorado about one-fifth.

A shifting of the relative positions held by the several states and territories as gold producers has taken place since the Eleventh Census. In 1889 California held the first rank; its product, as estimated by the Director of the Mint, was nearly four times as large as that of Colorado. While its production shows a small increase from year to year, yet it did not keep pace with the rapidly increasing production of Colorado, which in 1897 took the first rank and has retained it since. Alaska, which in 1889 was among the minor producers, in 1902 reached the third place, next to California.

No change has taken place in the relative positions of the three principal silver producing states, viz, Colorado, Montana, and Utah. But while the silver production of Colorado and Montana, after a period of increase up to 1895, shows a considerable decline, the silver production of Utah has substantially increased since 1889. Nevada and Idaho, which in 1889 occupied respectively the fourth and the fifth rank, have changed places, Idaho having kept up a steady increase. From 1889 to 1899 the silver production of Nevada sank into insignificance. Since 1900, however, there has been an increase, and in 1902 the silver production of Nevada was almost as great as in 1889. The variance previously referred to between the Census returns and Mint estimates for Arizona, Nevada, and Idaho accounts for the apparent decrease in 1902 of the gold production of Arizona and Nevada and for the increase of the silver production of Idaho.

It is interesting to note the relative places of the two precious metals in the principal gold and silver producing states in 1902. In Colorado a very notable change has taken place since the Eleventh Census. In 1889 the value of gold amounted to $3,883,859, and the coining value of silver to $23,757,751, which was equivalent—at the commercial rate of 93.5 cents per fine ounce[1]—to $17,500,000 in round numbers. In 1902 the value of the gold contents of Colorado ores was $26,414,800, while the commercial value of their silver contents was $7,740,227, which corresponded to a coining value of $19,617,392. Thus while the decrease of the commercial value of the silver product was nearly $10,000,000, the loss was made up by the increase in the value of the gold product, and there was a surplus of about $13,000,000 in the aggregate commercial value of both metals. The increase in the value of the gold and silver contents of the Colorado ores since 1889 amounted to 60 per cent.

In California and South Dakota the production of silver was insignificant, while in Montana and Utah the silver contents of the ores largely exceeded in value their gold contents.

Alaska.—The census of mines and quarries in 1902 did not extend to Alaska. Still, correspondence with the mining companies operating in the territory has brought replies covering all essential inquiries relating to deep mining for precious metals in the territory. There were in operation during the year 1902, 7 deep

[1] Report of the Director of the Mint on the Production of the Precious Metals, 1902, page 312.

gold and silver mines, all equipped with mills for the treatment of ores. A summary of these mines is presented in the following table:

[1] Includes $66,739 income from other sources.
[2] Income that can not be credited to mines or mills.

The bullion contents of gold and silver ore produced in 1902, as shown in the preceding table, were as follows: Gold, 126,327 fine ounces, valued at $2,609,143; silver, 7,828 ounces, valued at $3,638.

In addition to these quantities three copper mining companies reported to the Bureau of the Census the assay contents of their copper ore as follows: Gold, 370 fine ounces, worth $7,016; silver, 3,140 fine ounces, worth $1,567.

This makes in all 126,697 fine ounces of gold, valued at $2,616,159, and 10,968 ounces of silver, valued at $5,205. The Mint agents estimated the product of Alaska deep mines as follows: Gold, 124,156 fine ounces; silver, 89,388 fine ounces.

The Census returns from producers exceed the Mint agents' estimate of the gold product by 2,541 ounces. The Mint agents' estimate of the silver product of deep mines is many times in excess of the Census returns from producers. Inasmuch as no allowance is made in the silver estimate for the silver contents of placer bullion, which on a gold product of about $2,500,000 must be considerable, it is apparent that the estimate is meant to comprise the silver contents both of ore and of placer bullion. The product of placer mines is estimated by the Mint agents at 276,554 fine ounces.

The total product of Alaska in 1902, as estimated by the Director of the Mint, is somewhat above that of the Mint agents, viz: Gold, 403,730 fine ounces, worth $8,345,800; silver, 92,000 fine ounces, worth $118,950. This estimate is accepted by the Bureau of the Census.

The growth of the gold production of Alaska since 1890 is shown in the following table, compiled from the annual reports of the Director of the Mint on the production of the precious metals. The statistics for some years include silver; the percentage of silver in Alaska ores is, however, so insignificant that the error may be disregarded.

TABLE 71.—*Production of gold in Alaska: 1890 to 1902.*

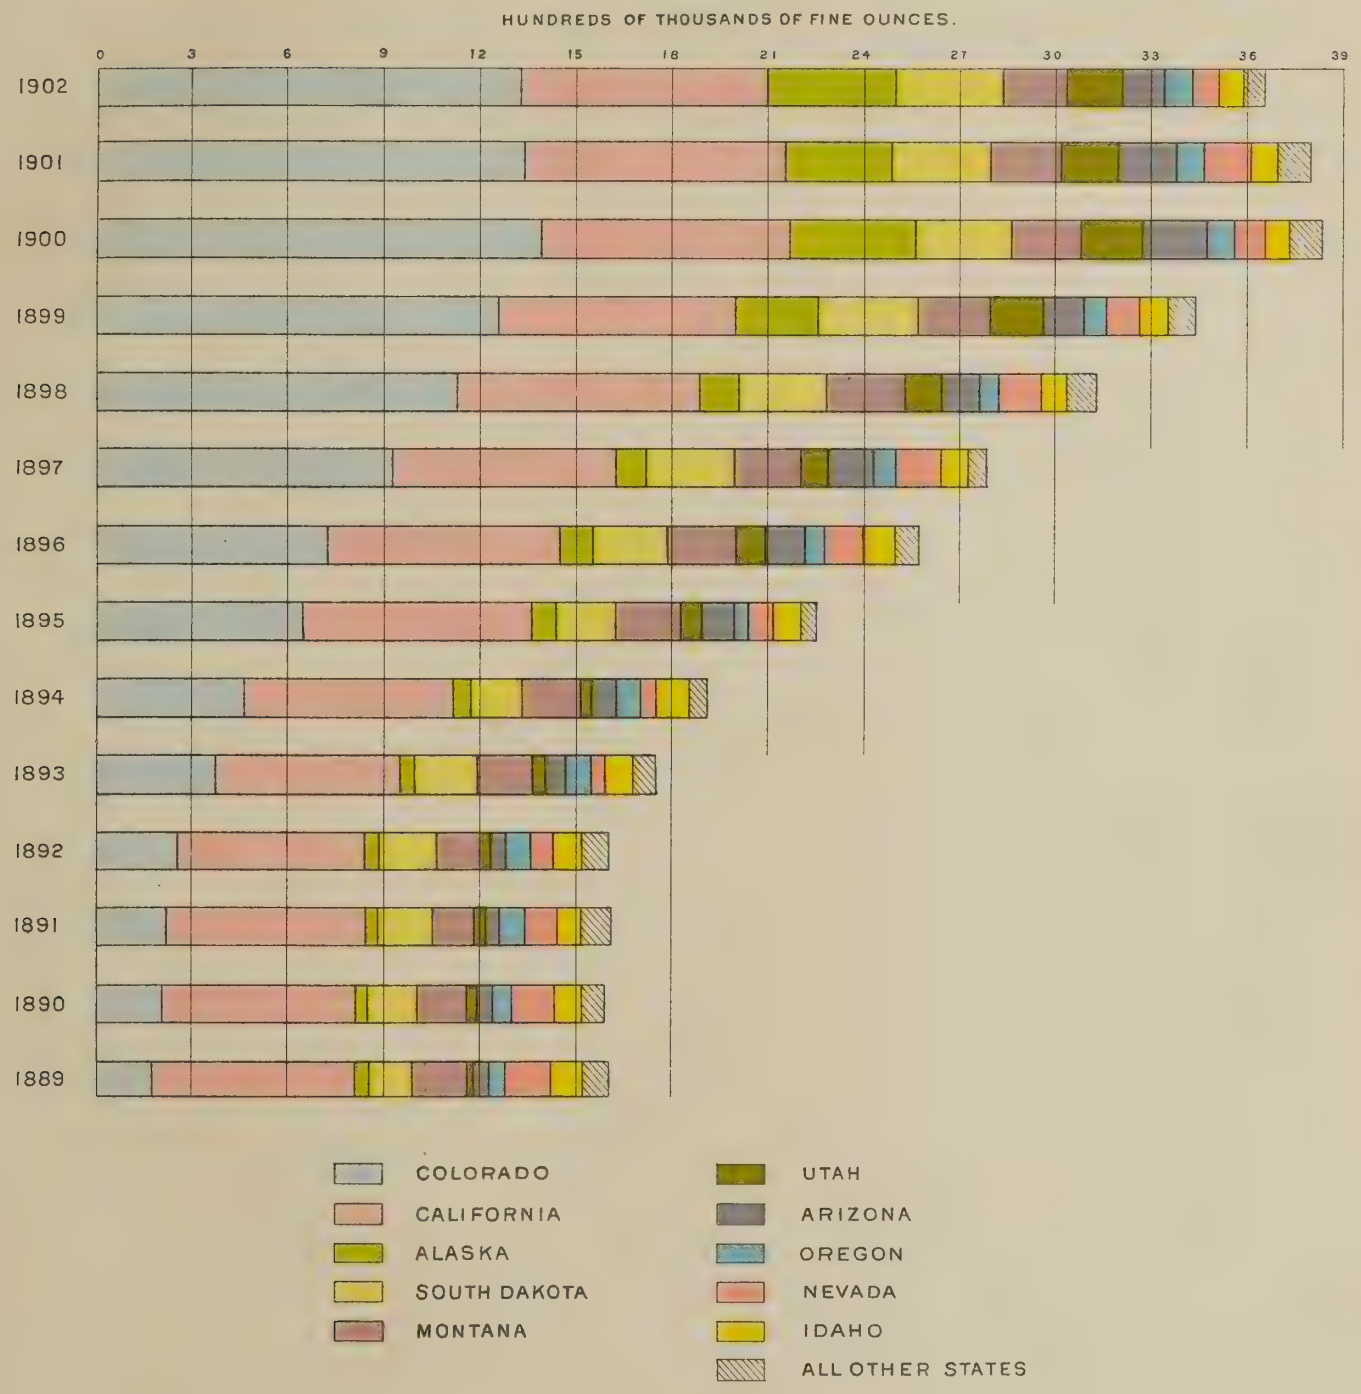
[Compiled from Report of Director of the Mint.]

Year.	Total value.	Quartz.	Placer.
Total	$44,610,473	$18,747,306	$25,863,167
1890	762,429	687,429	75,000
1891	1,020,045	880,045	140,000
1892	1,080,446	845,046	235,400
1893	1,038,824	779,782	259,042
1894	1,282,623	759,350	523,273
1895	2,328,419	1,311,337	1,017,082
1896	2,861,307	1,370,862	1,490,445
1897	2,439,582	1,760,793	678,789
1898	2,517,121	1,010,356	1,506,765
1899	5,831,355	2,704,176	3,127,179
1900	8,166,187	2,089,818	6,076,369
1901	6,998,726	1,981,775	5,016,951
1902	8,283,409	2,566,537	5,716,872

The preceding table shows that the growth of Alaska as a gold mining district is chiefly due to the development of placer mining, which has, since 1898, outrun the production of deep mines, whereas previous to 1898 the placer production amounted to 34.5 per cent of the total output. The share of placer mines in the total production for 1898 to 1902 amounted to 67.4 per cent.

The history of deep mining in Alaska is practically a record of the work of three companies, the Alaska Treadwell, the Alaska-Mexican, and the Alaska United gold mining companies, which are controlled by the same interests and operated under a joint management. The annual statements of these companies to their stockholders set forth in minutest detail the accounts of their operations and furnish an instructive example of the successful mining of low-grade ores. By courtesy of

DIAGRAM III.—PRODUCTION OF GOLD: 1889 TO 1902.



President William Alvord, the Bureau of the Census has been given the privilege of using these statements in the present report.

The Alaska Treadwell Gold Mining Company is the oldest of the three companies. It is incorporated with a capital stock of $5,000,000, divided into 200,000 shares of $25 each, all issued. The mine has been in active operation since August, 1885, and yielded during that time $13,484,311 in gold, at an average of $2.57 per ton; the operating costs for the same period averaged $1.29 per ton. The operating profits aggregated $6,742,149.58, and have thus more than repaid the entire capital stock at its par value. The yield per ton has been declining, but the operating costs have also been materially reduced, while the tonnage crushed has more than trebled since 1890. As a result, the company's operating profits for the year 1902 were considerably larger than in years past when the yield per ton was higher. The progress in the methods of treating the ore is evidenced by the fact that while the yield in free gold has been steadily decreasing, the value saved by reworking the ore after the free gold is extracted shows a marked increase both in amount and in proportion to the total recovery. The results accomplished by the company are shown in the following statement:

Bullion shipments from Paris or Treadwell mine: 1890 to 1902.

[From beginning of work to May, 1903.]

DATE.	Tons crushed.	YIELD.			Operating profits.	Yield per ton.	Operating costs per ton.
		Total.	Free gold.	Concentrates (sulphurets).			
Total	4,624,289	$11,144,912.24	$7,069,917.85	$4,074,994.39	$5,667,149.58	$2.41	$1.18

1899-1900, June to May	557,960	1,153,367.60	773,165.69	380,201.91	669,301.20	2.07	0.86
1900-1901, June to May	457,802	860,736.58	559,126.37	301,610.21	377,417.34	1.88	1.05
1901-2, June to May	682,893	1,304,720.54	665,591.27	639,129.27	481,633.94	1.91	1.20
1902-3, June to May	756,325	1,598,963.42	785,515.13	813,448.29	659,849.77	2.11	1.24

The total assay value of the ore treated at the company's two mills during the fiscal year ending on May 15, 1903, was $1,697,507, and the total net value recovered in the mills was $1,613,991—i. e., about 95 per cent of the assay contents. The total yield per ton for the same year was $2.11, of which $1.04 was free gold and $1.07 was saved in sulphurets. The average value of sulphurets per ton after concentration was $52.58. The net profit for the year was $692,208.94, out of which $375,000 were paid in dividends during the year. The amount written off for depreciation was $448,493. During the year there was an average of 33 machine drills at work in the mine. The average number of drills used in mining the ore (stoping) was 14.5. The others were used in development and other kinds of work. The average work of one machine per shift of ten hours was 38 tons.

The Alaska-Mexican Gold Mining Company is incorporated with a capital stock of $1,000,000, divided into 200,000 shares of $5 each, of which $900,000 are outstanding. The mine has been in active operation since 1894, and has yielded during that time $2,816,279 in gold, at an average of $2.18 per ton. The operating cost averaged for the same period $1.73 per ton. The operating profits aggregated $587,912, out of which $465,381 were paid in dividends. What has been said above of the Alaska Treadwell Mining Company in regard to the grade of ore and the values recovered in sulphurets is likewise true of the Alaska-Mexican mine, as shown by the following statement:

Bullion shipments from Alaska-Mexican mine: 1894 to 1902.

[From beginning of operations to December 15, 1902.]

YEAR.	Tons crushed.	YIELD.			Operating profits.[1]	Total yield per ton.	Operating costs per ton.	Operating profits per ton.
		Total.	Free gold (including base bars).	Concentrates (sulphurets).				
Total	1,293,662	$2,816,278.83	$1,859,261.20	$957,017.63	$587,911.92	$2.18	$1.73	$0.45
1894	73,141	204,042.46	154,643.33	49,399.13	60,215.60	2.79	1.97	0.82

1898	162,457	375,882.36	257,484.67	118,397.69	100,663.07	2.31	1.69	0.62
1899	166,054	347,414.97	231,841.23	115,573.74	62,333.42	2.09	1.73	0.38
1900	166,449	315,005.45	233,105.08	81,900.37	33,821.02	1.89	1.69	0.20
1901	178,960	339,452.31	213,923.07	125,529.24	24,709.63	1.90	1.76	0.14
1902	207,455	426,732.56	216,772.25	209,960.31	86,025.51	2.06	1.64	0.41

[1] Included in the operating profits is a total of $3,573.79, distributed as follows: Profit on sale of 31,000 shares of stock in 1893, $575.95; interest received in 1898, $694.46; interest received in 1899, $1,682.76; interest received in 1900, $620.62.

The grade of ore mined in 1902 was the same as that of the Alaska Treadwell Gold Mining Company. The average value per ton was $2.06, of which $1.04 was recovered in free gold and $1.02 was saved in sulphurets. The average value of sulphurets per ton, after concentration, in 1902 was $59.51. The net profit for the year was $86,025.

The following summary is compiled from the profit and loss accounts of the Alaska Treadwell Gold Mining Company for the year ending May 31, 1903, and the Alaska-Mexican and the Alaska United gold mining companies for the calendar year 1902:

Profit and loss account of the Alaska Treadwell, Alaska-Mexican, and Alaska United gold mining companies.

	Alaska Treadwell (year ending May 31, 1903).	Alaska-Mexican (calendar year 1902).	ALASKA UNITED.	
			Ready Bullion Mine (calendar year 1902).	Seven Hundred Foot Mine (calendar year 1902).

[1] Includes cost of development work.
[2] Includes cost of concentrating 3,792.27 tons sulphurets.
[3] Includes cost of concentrating 4,640 tons sulphurets.
[4] Includes cost of concentrating 2,188 tons sulphurets.
[5] $0.1150 per ton of reconstruction work.

The Alaska United Gold Mining Company is the youngest of the three companies. It began operations on the Ready Bullion claim in November, 1898, and on the Seven Hundred Foot claim in April of the following year. The total yield of the former from beginning of operations to December 15, 1902, aggregated $1,539,480, averaging $2.03 per ton. The operating cost averaged $1.72 per ton and the operating profits 31 cents per ton.

The Seven Hundred Foot claim produced from the beginning of operations to December 15, 1902, $665,376 in gold and base ores, averaging $1.59 per ton; the operating cost averaged $1.56 per ton, leaving a profit of 3 cents per ton. The company was capitalized at $1,000,000, divided into 200,000 shares of $5 each, of which $901,000 are outstanding. The total operating profits since organization amounted to $250,491. There was a deficit for the year on the Ready Bullion claim amounting to 2 cents per ton, but the construction account on the same mine, charged to current expenses, likewise averaged 2 cents per ton.

California.—California had more operators than any other state, viz, more than one-third of the total number reported for the United States. Eliminating from the latter total the 447 argentiferous lead mines and considering only gold and silver mines, California had about two-fifths of the total number of operators reported for the United States. This does not include small operators from whom no individual reports were received; the latter were also located chiefly in California. Of the total estimated value of the product of small mines, 70 per cent, viz, $1,130,158, was reported from California. It is therefore a fair estimate that there were in 1902 more operators of gold mines in California than in all other states and territories, Alaska not being included in the comparison.

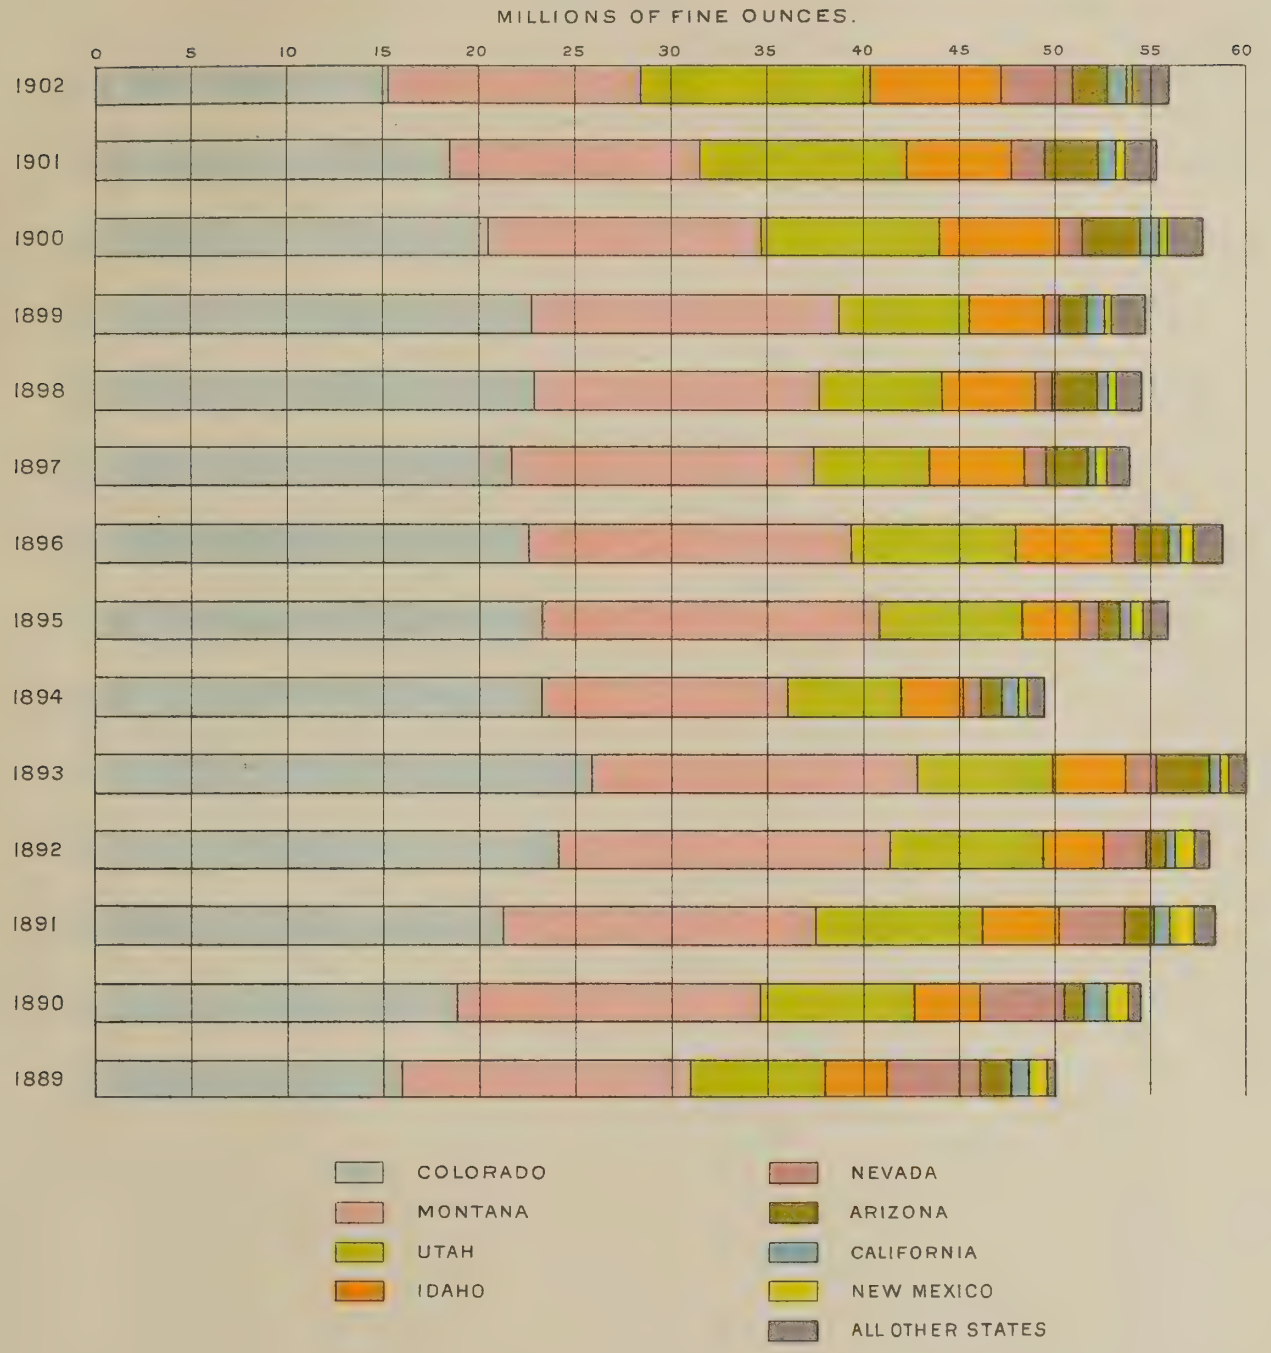
The majority of mine operators in California were interested in placer mines; measured by their output, however, the placer mines of California were of minor importance in comparison with the deep mines of the state. Small operators employing no hired labor were still very numerous in 1902 among the owners of placer mines. Reports were received from 316 mines operated without hired labor; each mine was worked on the average by two owners; the average value of product per mine was $924. Two-thirds of the product of this class of operators was obtained from placer mines. Where deep mines were worked without hired labor, only high-grade ore, averaging $25 per ton, was treated.

Most of the deep mines were equipped with mills for the treatment of their ores. Those which had no facilities for the treatment of their ores were very small, employing an average of about two men throughout the year; their annual production averaged only about $3,000 per mine. They treated only high-grade ore, averaging $24 per ton. Those mines which were provided with milling facilities were able to treat ores averaging $5 per ton; their annual production averaged $43,720 per mine.

There were among the operators 31 incorporated companies by which dividends were declared in 1902, aggregating $1,099,399, and averaging 4 per cent on the total outstanding capital stock. The ore treated by these companies was of a low grade, averaging only a little over $7 per ton. Their total production for 1902 was valued at $4,866,812, or an average of $156,994 per mine.

The tendency toward concentration of production was pronounced. Thirty-two of the operators, each with an output of $100,000 or over, produced more than one-

DIAGRAM IV.—PRODUCTION OF SILVER: 1889 TO 1902.



half (52.8 per cent) of the total product, whereas all small producers (those whose output was less than $1,000, as well as those of a shifting character who made no individual reports) contributed in all 8.3 per cent of the total output of the state.

The tables which follow present the principal statistical facts for California. Table 72 is a comparative summary for deep mines with and without mill connection; arrastras, custom mills, and mines run exclusively on old tailings are not included in the comparison. Table 73 is a summary for placer mines, exclusive of 7 mines connected with stamp mills. Table 74 is a summary for 316 mines operated by the owners without hired labor, and Table 75 is a summary for dividend paying mines.

Amount received for custom work	$30,788
Total value of product	$4,866,812
Average per mine	$156,994

Colorado.—In 1902 Colorado was the principal gold and silver producing state. Only the largest mines had their own reduction works; their number was less than one-tenth of the total number of mines in the state, while their product amounted to over two-fifths of the total for the state. The average grade of ore treated at mills connected with mines was valued at $9 per ton, whereas the ore shipped from mines without mills of their own was worth $20 per ton.

About one-half of the mines without mill connections expended more during 1902 than the value of their product. The average value of their ore was the same as in other mines of the same class, viz, $20 per ton; the treatment charges and freight averaged with them $7.16 per ton, and with others $6.42 per ton. Apparently there was no difference, either in the grade of their ore or in their location, which would place them at a disadvantage as compared with other mines. It is therefore fair to assume that the surplus expenditure was invested in development work.

The leasing system is a prominent feature in Colorado. The total amount of royalties for mine and mineral lands reported by operators whose mines were located exclusively on leased land was $379,521, and the aggregate value of their product at the mines was $2,190,840. Thus the average rate of royalties was 17.3 per cent. The average production per mine in 1902 was valued at $11,352.

This number of lessees does not comprise the class of small operators locally known as "leasers," "block lessees," etc., and designated in this report as "share workers." Two-thirds of the total number of such operators in the United States, viz, 814 out of 1,230, were reported from Colorado. The total amount realized by them, after deducting royalties, was $1,106,602, making an average of $1,359 per "lease." A concise description of the system of mining on shares was furnished by Mr. Kenneth McKenzie, vice-president and general manager of the Acacia Gold Mining Company, Cripple Creek, Teller county, Colo., in a communication dated May 19, 1903, in reply to an inquiry from the Bureau of the Census. "There are generally from 2 to 6 men interested in a lease; some of them work out for wages and divide up their wages with their partners working on the leased ground until they find ore enough to pay expenses, which very often they never do. Many of the men would be working for half wages and an interest in the lease. All properties that are operated by lessees in the Cripple Creek district are worked much the same as ours."

There were 47 incorporated companies which declared dividends in 1902. The total amount of dividends paid by them was $3,689,444, averaging 5.2 per cent on the par value of an outstanding capital stock of $70,753,173. The total value of their product was $13,801,413—i. e., nearly one-half of the total product of the gold and silver mines of the state; the average per mine was $293,647. The ore mined by them was of a high grade, averaging $20 per ton.

The tendency toward concentration was quite pronounced in Colorado. Sixty-four mines each producing $100,000 or more contributed over four-fifths (80.4 per cent) of the output of the state; 279 operators each producing less than $1,000 contributed only three-tenths of 1 per cent; and 429 with a product ranging from $1,000 to $100,000 produced less than one-fifth.

The principal statistical data for Colorado are presented in Tables 76, 77, 78, and 79. Table 76 is a comparative summary of deep mines with and without mills; productive mines, and mines where the work was chiefly development, are shown in separate columns. Table 77 is a summary of deep mines operated on leased land only. Table 78 is a comparative summary of mines worked on shares with and without hired labor. Table 79 is a summary for dividend paying companies.

Total value at mine	$13,801,413
Average per mine	$293,647

Idaho.—About one-half of the mines of Idaho were placers, viz, 127, of which number 53 were operated without hired labor. The number of owners working was 92, and the average number of wage-earners employed was 199. The total value of the product was $302,175, an average of $2,379 per mine.

One-half of the deep mines were equipped with mills. These were the larger mines, the production of which averaged over $100,000 per mine. The ore treated was of a low grade, averaging about $9 per ton. The mines without mills were of the small type, with an annual product averaging less than $10,000 per mine. The ore treated by them was of a very high grade, averaging $60 per ton.

There were 10 incorporated companies which paid dividends in 1902. The total amount of dividends paid was $880,271, which was equal to 7.9 per cent on an outstanding capital stock of $11,130,420. The ore treated by these companies was of an average value of $11 per ton. The average production per mine was $358,175.

Concentration of ownership has made greater progress in Idaho than in other states. Five-eighths, $5,123,859, of the total output was contributed by 6 operators, each having an output valued at more than $500,000; one-fifth, $1,648,164, was contributed by 6 operators, each with an output valued at from $100,000 to $500,000. Very small operators, producing less than $1,000, including those from whom no individual reports were received, contributed only 1.4 per cent.

The principal statistical data for Idaho are given in the tables which follow. Table 80 is a comparative summary for deep mines operated with and without mills; Table 81 is a summary for argentiferous lead mines; Table 82 is a summary for dividend paying productive mines.

Nevada.—Nevada was at one time the principal silver mining state. The famous Comstock lode in the early days of its history furnished more than one-half of the total silver production of the United States. The flooding of the lower levels of the Comstock lode in 1886 reduced silver mining in Nevada to insignificant proportions at a time when the price of silver was nearly twice as high as in 1902. The technical progress of recent years, however, has made it possible to resume mining on the submerged levels even with the present low price of silver.

The bulk of the product mined in Nevada in 1902 was high-grade ore carrying gold and silver, and averaging $62 per ton; this ore was shipped in crude state. There were 16 mines provided with reduction plants where low-grade ore was treated.

There were 6 incorporated companies which declared dividends in 1902. The total dividends paid by them amounted to $77,602, which was equal to an average of 2.8 per cent on an outstanding capital stock with a par value of $2,748,000. The average production per mine for these companies was a little over $250,000; the ore treated by them was of a very high grade, averaging $73 per ton.

The working of the deeper mines in Nevada required a large investment of capital; hence the necessity of producing on a large scale. Three-fifths of the total yield for 1902 was produced by 5 operators, each with an output valued at $100,000 or over; the production of 1 of these 5 mines was worth over $1,000,000.

The principal statistical data for Nevada are presented in the following tables. Table 83 is a comparative summary for deep mines with and without mills, and Table 84 is a summary for dividend paying mines.

The following is a tabular statement showing the production of the Comstock lode for 42 years, from its discovery in 1859 to the close of 1900.[1] The statistics for the earlier years are estimates based upon reports by locators and producers as substantiated by data given by millmen, and Wells, Fargo & Co., and by the county assessors' records. The results are thought to be substantially correct.

[1] Prepared by Alfred W. Doten: Report of Director of the Mint on the Production of the Precious Metals, 1900, pages 162 and 163.

Comstock total gold and silver production, from discovery and commencement: 1859 to 1900.

YEAR.	Ore (tons).	Gold, value.	Silver, value.	Total value.	Average per ton.
1859		$30,000.00		$30,000.00	
1860	10,000	550,000.00	$200,000.00	750,000.00	$75

1900	35,300	381,423.56	319,441.70	700,865.26	20
Total	10,698,681	146,613,877.61	203,636,062.84	350,249,940.45	
Total mill tailings added				17,763,863.16	
Grand total				368,013,803.61	

As the above statement shows, the higher grade ores became exhausted by 1881, when the average value per ton fell by nearly one-half. There was a temporary increase in 1888 due to finds of rich ore. In 1900 the production seemed to be on the increase. The total production has been valued by some as high as $500,000,000. This lode has produced nearly as much gold as silver.

The statement below, drawn from the same source as the one preceding, shows the financial results of forty years' mining operations in the Comstock lode.[1] All the mines are arranged in three groups: (1) Those whose investments as represented by assessments were repaid by dividends. (2) Those whose dividends failed to repay assessments. (3) Those which paid no dividends.

[1] Report of Director of the Mint on the Production of the Precious Metals, 1900, page 159.

Forty years' assessments and dividends of Comstock mines.

CLASSIFICATION OF MINES WITH REGARD TO ASSESSMENTS AND DIVIDENDS.	Number of mines.	Total assessments.	Total dividends.
Total	28	$79,045,097	$133,101,590
Dividends in excess of assessments	5	10,635,650	117,620,200
Dividends short of assessments	9	40,238,684	15,481,390
No dividends paid	14	28,170,763	

The preceding statement brings out the fact that only 5 companies returned their investment with profit; 9 companies have paid dividends, not sufficient, however, to repay for the capital invested, while one-half of the Comstock companies never recovered the capital invested. That so much capital was found for investment in obviously unprofitable ventures is thus explained by Mr. Doten: "The regular assessments levied upon the nonpaying mines were paid with the utmost facility by the market itself, delinquent assessments being immediately added to the price of the stock, fortune-blinded dealers hardly knowing or caring how it was done or who paid it, and it is to this recklessness of stock speculations that many of their mines owe their very existence to-day."

WORLD'S PRODUCTION OF GOLD AND SILVER IN 1902.

Table 85 represents the world's production of refined gold and silver in 1902, as estimated by the Director of the Mint.

It shows that as a producer of gold the United States held the second rank, being preceded by Australasia; South Africa followed next, the fourth rank was held by Russia, and the fifth by Canada. Great Britain with her colonial empire produced, in round numbers, $154,000,000, or more than one-half of the total output of the world, and the United States followed next with $80,000,000, or more than one-fourth; both nations together contributed four-fifths of the product of the gold mines of the world.

Mexico was the leading silver producing country, the output of her mines exceeding one-third of the world's production; the United States followed close behind, with one-third of the world's output. North America contributed 71.9 per cent of the world's production, and Central and South America 14.1 per cent, making for the entire American continent six-sevenths of the silver product of the world.

The following table shows the silver production of the mines and smelters of the world from 1889 to 1901. The mines of the United States and Mexico produce about two-thirds of the world's supply of silver. The United States smelts and refines all silver exported from Mexico and Canada and a portion of the production of Central and South America. Great Britain, Germany, and Belgium together import about one-half as much silver ore as the United States. The countries from which they draw their supply of ore are chiefly Australia and South America.

TABLE 86.—WORLD'S PRODUCTION OF SILVER FROM MINES AND SMELTERS: 1889 TO 1901.

[Figures for 1893 to 1901 from "Lead, Copper, Spelter, Tin, Silver, Nickel, Aluminum, and Quicksilver," compiled by Metallgesellschaft and Metallurgische Gesellschaft, A.-G., Frankfort-on-the-Main, October, 1903; those for 1889 to 1892 from "Summary of the Statistical Report of the Metallgesellschaft."]

PRODUCTION OF LEAD.

Lead contents of ores smelted in the United States, 1894 to 1902.—A considerable part of the value of the total output of silver mines is the value of the lead contents of their ores. In many cases the value of the lead contained determines whether or not an ore can be mined with profit; and, therefore, statistics of lead are of direct interest in connection with silver.

About three-fourths of the entire output of refined lead in the United States is obtained from silver bearing ores, as appears from the following table. The ores of Missouri, Kansas, Wisconsin, Illinois, Iowa, Virginia, and Kentucky are nonargentiferous; all others are argentiferous.

TABLE 87.—LEAD CONTENTS OF ORES SMELTED BY THE WORKS IN THE UNITED STATES, BY STATES AND TERRITORIES: 1894 TO 1902.

World's production and consumption of lead, 1889 to 1902.—The following table shows the world's production and consumption of lead, by countries, from 1889 to 1902:

TABLE 88.—WORLD'S PRODUCTION AND CONSUMPTION OF LEAD: 1889 TO 1902.

[Production figures from "Lead, Copper, Spelter, Tin, Silver, Nickel, Aluminum, and Quicksilver," compiled by Metallgesellschaft and Metallurgische Gesellschaft A.-G., Frankfort-on-the-Main, October, 1903. Consumption figures from 1889 and 1892 from "Summary of the Statistical Report of the Metallgesellschaft;" those for 1893 to 1902 from "Metallgesellschaft and Metallurgische Gesellschaft," October, 1903.]

[1] For production, includes lead contents of the ores exported.

[2] For production, the figures comprise the lead obtained from Canada ores in the United States, as well as the Canadian exports of argentiferous lead which were not imported till 1900, in which year, however, the amount rose to 10,000 tons; for 1901 and 1902 no figures were obtainable.

[3] For production, Russia, Scandinavia, and Turkey.

[4] For production, such as was not exported to Europe and America has not been taken into account here. The total production of Australia amounted in 1902 to 90,000; 1901, to 90,000; 1900, to 87,100; 1899, to 87,600; and in 1898, to about 67,000 metric tons. The exports of lead from Australia to eastern Asia amounted to about 11,700 in 1902, 9,100 in 1901, and 12,500 metric tons in 1900.

[5] For production, imports from Chile, Peru, East India, and Africa to Europe, according to European Trade Statistics.

[1] For production, includes lead contents of the ores exported.

[2] For production, the figures comprise the lead obtained from Canada ores in the United States, as well as the Canadian exports of argentiferous lead which were not imported till 1900, in which year, however, the amount rose to 10,000 tons; for 1901 and 1902 no figures were obtainable.

[3] For production, Russia, Scandinavia, and Turkey.

[4] For production, such as was not exported to Europe and America has not been taken into account here. The total production of Australia amounted in 1902 to 90,000; 1901, to 90,000; 1900, to 87,100; 1899, to 87,600; and in 1898, to about 67,000 metric tons. The exports of lead from Australia to eastern Asia amounted to about 11,700 in 1902, 9,100 in 1901, and 12,500 metric tons in 1900.

[5] For production, imports from Chile, Peru, East India, and Africa to Europe, according to European Trade Statistics.

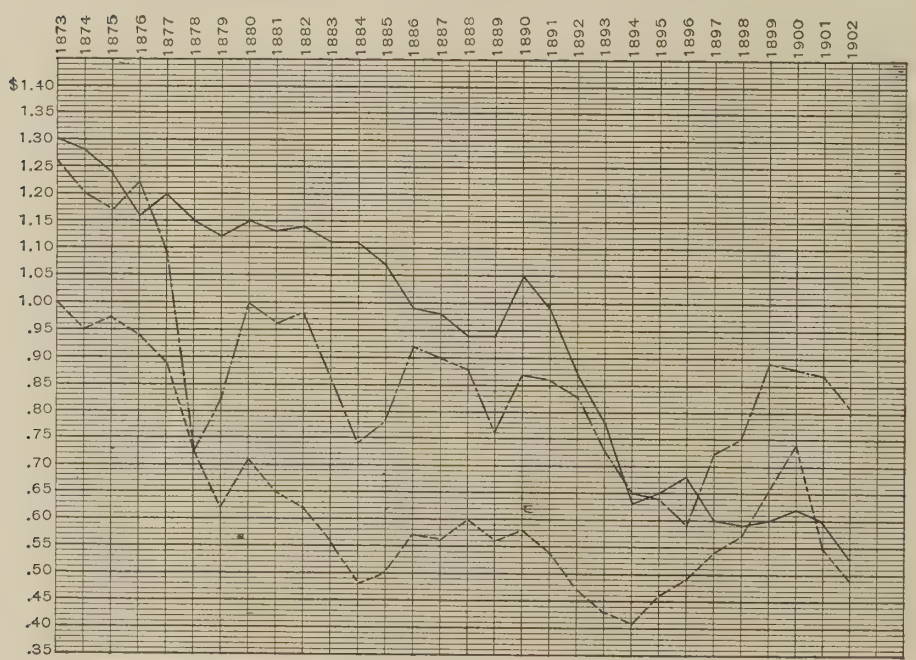
——— AVERAGE PRICES OF SILVER, CENTS PER OUNCE.
– – – – AVERAGE PRICES OF LEAD, CENTS PER UNIT OF 20 POUNDS, IN LONDON MARKET.

DIAGRAM VII.—PRICES OF SILVER AND LEAD IN THE LONDON MARKET, AND LEAD IN THE NEW YORK MARKET: 1873 TO 1902.



——————— AVERAGE PRICES OF SILVER, CENTS PER OUNCE.
— — — — — AVERAGE PRICES OF LEAD, CENTS PER UNIT OF 20 POUNDS, IN NEW YORK MARKET.
— — — — — AVERAGE PRICES OF LEAD, CENTS PER UNIT OF 20 POUNDS, IN LONDON MARKET.

The foregoing table shows that the United States is both the largest producer and the largest consumer of lead. Spain, Germany, Mexico, and Australia, respectively, rank next as producers, while Great Britain, Germany, and France follow in this order as consumers. More than one-half of the world's lead output is consumed in the lead producing countries, less than one-half being an article of international commerce. The largest producer for the world's market is Spain, which furnished in 1902 about one-half of the supply; next after Spain follows Mexico, and the third place is occupied by Australia. These three countries together furnish the supply for about nine-tenths of the international demand for lead. The largest consumer of imported lead is Great Britain, which in 1902 consumed more than one-half of the international supply. The second place is held by France. The two countries together have imported within late years from two-thirds to three-fourths of the entire quantity sold in the world's market. The United States produces lead for home consumption only, and imports a comparatively small proportion for the same purpose; but a considerable quantity of lead ores and base bullion is imported from Mexico and British America, refined in bond, and reexported.

The following table shows, by years, the share of the United States in the lead exports of Mexico and British America. The first column represents the excess of the product of Mexico and British America over their consumption, as shown in the preceding table, the quantities being reduced from metric to short tons. The second column represents the production of refined lead in the United States from foreign ores and base bullion, less the imports of ore and base bullion from other countries than the two above named; both quantities are taken from the estimates of the United States Geological Survey.

TABLE 89.—*Total exports of lead ore and base bullion from Mexico and British America, and exports from those countries to the United States: 1889 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

YEAR.	TOTAL EXPORTS.	EXPORTS TO THE UNITED STATES.	
	Short tons.	Short tons.	Per cent of total exports.
1902	122,212	98,008	80.2
1901	124,526	108,281	87.0
1900	120,889	103,281	85.4
1899	104,249	95,355	91.5
1898	94,331	99,705	105.7
1897	95,764	82,891	86.6
1896	79,675	76,910	96.5
1895	79,675	75,707	95.0
1894	62,814	59,739	95.1
1893	70,528	65,351	92.7
1892	52,345	39,957	76.3
1891	33,280	23,852	71.7
1890	24,575	18,124	73.7
1889	30,305	26,570	87.7

The preceding table shows that the United States received about nine-tenths of the exports from Mexico and British America. In 1898 the lead product smelted in the United States from Mexican and Canadian ores exceeded the total exports from those countries; this is explained by the fact that a portion of the ore smelted during that year had been exported during the year previous.

Prices of silver and lead.—Diagram V shows the annual fluctuations of the commercial ratio of gold to silver since the beginning of the eighteenth century. The fluctuations in the price of an ounce of standard silver, 0.925 fine, in the London market in 1901 and 1902 are shown in the following statement:[1]

Prices of silver in London by months: 1902 and 1901.

	1902	1901
	d.	d.
January	25.69	28.98
February	25.42	28.14
March	25.01	27.94
April	24.32	27.30
May	23.70	27.45
June	24.17	27.42
July	24.38	26.96
August	24.23	26.94
September	23.88	26.96
October	23.40	26.61
November	22.69	26.09
December	22.21	25.44

Diagrams VI and VII show the fluctuations of the prices of silver and lead for two periods of equal length divided by the year 1873, when silver began to decline in value. Diagram VI shows the prices in the London market of an ounce of fine silver and of a unit of 20 pounds of lead. Diagram VII shows the London prices of silver and lead and the New York price of lead since 1873.

An examination of the diagrams shows that the prices of lead and silver move in different directions: though the bulk of silver as well as of lead in the United States is smelted from ores where both metals occur together, yet their price movements in the United States show no similarity; on the other hand, the movements of the London and the New York price of lead are approximately parallel.

Tables 90 and 91 are detailed summaries of the statistics for gold and silver mines for 1902, the former for producing mines, the latter for mines at which the work was only development.

DESCRIPTIVE.

The production of gold and silver antedates the dawn of written history. The search for the precious metals prompted the discovery of new continents and stimulated the efforts of the alchemists, thus indirectly lead-

[1] "Comparative Statistics of Lead, Copper, Spelter, Tin, Silver, Nickel, Aluminum, and Quicksilver," compiled by Metallgesellschaft and Metallurgische Gesellschaft, A.-G., Frankfort-on-the-Main, October, 1903.

ing to the development of scientific chemistry. Yet it is only since the beginning of gold mining in English-speaking countries, at about the middle of the nineteenth century, that any progress in mining methods can be recorded. And even to-day, notwithstanding the technical advance of the last half century, mining methods of primitive man can be observed in actual operation in some parts of the United States.

Placer mines.—The earliest form of gold mining is the working of alluvial mines or "placers," where the gold has been reduced by the operation of the forces of nature to fine dust mixed with gravel. The work left for the miner is to separate by washing the particles of gold from the surrounding mass of sand and gravel. The final product of the mine is gold.

The pioneers of gold mining in the United States had no experience to guide them but that of the Latin-American countries. The results accomplished by the Spaniards were extremely meager. Mr. T. Wain-Morgan Draper, writing in the Engineering and Mining Journal concerning the gold deposits in Ecuador and Colombia, cites the example of one property which was worked extensively with numerous slaves for over one hundred years. A careful examination and measurement of the work accomplished shows that half a dozen 4-inch "giants" would do as much in one year's time. No such results could be accomplished by the Spaniards with their tiny reservoirs, which, when filled with rain water, were turned loose to wash the gravel down a rock sluice.[1] During the canvass of 1903 there was found in Arizona a placer field of 7,000 acres, divided into numerous claims, worked by Mexicans, where not only was all work done by hand, but even the water was packed or hauled from a distance of 6 or 8 miles.

The beginning of gold mining in the United States dates back to the first quarter of the nineteenth century, when some placer mining was done in North Carolina and Georgia. The settlers worked at odd moments singly or in small gangs, giving to mining such time as they could spare from other occupations. The workings were largely executed by slave labor and were confined chiefly to surface mining.

The gold pan, the long tom, the rocker, and the pick and shovel constituted the miner's outfit. These simple methods still survive wherever placers are worked by miners with practically no capital and without hired labor. It may be fairly estimated that most of the placer gold mined in the Western states and Alaska is produced in this time honored fashion. The following extract, descriptive of placer mining as it was conducted in Alaska as late as 1900, is quoted from an official report:[2]

> The mining on the beach is the simplest operation possible, a rocker being all that is required in addition to a shovel and a pick and a good, strong back. The dirt is shoveled up and thrown onto a coarse screen, which removes the larger stones and trash, the latter derived from the driftwood, etc., from the sea. The fine dirt passes over a series of riffles, which are small obstructions, and is finally washed off, leaving the heavy gold. In some cases the tailings pass over a small piece of carpet or burlap, in other cases an amalgamated silver plate is used; but in each case the object is the same, viz, to catch the fine gold. The heavy particles of gold are caught in the riffles, while the fine either amalgamates or is retained by the carpet, while the lighter material or tailings is washed away.

Soon after the discovery of gold in California, however, the inventive genius of the American miner devised a simple but effective way of working placer mines. The first hydraulic apparatus for working placer mines was introduced in the spring of 1852 by a miner, whose name is not remembered, at his claim at Yankee Jim, Placer county, California.

> This machine was very simple. From a small ditch on the hillside a flume was built toward the ravine, where the mine was opened. The flume gained height above the ground as the ravine was approached, until finally a "head," or vertical height, of 40 feet was reached. At this point the water was discharged into a barrel, from the bottom of which depended a hose, about 6 inches in diameter, made of common cowhide, and ending in a tin tube about 4 feet long, the latter tapering down to a final opening or nozzle of 1 inch. This was the first hydraulic apparatus in California, simple in design, dwarfish in size, yet destined to grow out of its insignificance into a giant powerful enough to move mountains from their foundations. The news spread among the miners, the wonderful practicability of the new invention was at once acknowledged, and, wherever circumstances permitted, a "hydraulic," the name adopted for the novel apparatus, was rigged.[3]

The original idea was much improved upon in the course of time, and the hydraulic method proved a great labor saver, as compared with the primitive pan, rocker, and sluice. The decline of hydraulic mining within the last twenty years is the outcome of a long conflict between the farming and mining interests in California, which has resulted in the débris legislation for the protection of navigable rivers and farming lands. Hydraulic mining requires great space for dumping the masses of earth which are removed from their original position. Formerly, after a bank had been broken up and the gold washed out, the easiest way to get rid of the "tailings" was to discharge them into the nearest stream. With the extension of hydraulic mining the rivers were soon overfilled with débris, which settled in their beds and was deposited all along their course, causing considerable damage to abutting farm lands. An act of Congress was passed in 1893 which requires débris or tailings of all mines operating in the drainage basins of the Sacramento and San Joaquin rivers to be impounded behind dams or other restraining works. This restricts the output, as not nearly as much gravel can be washed in a given time with a given quantity of water as when the débris

passed away and took care of itself without having to be impounded.

When the first surface diggings were exhausted, attention was turned to deep lying auriferous gravels which are overlaid by a capping of volcanic rock or by a deep stratum of barren gravel. These mines are worked by drifting.

The "drifting" process consists in running long tunnels under the lava-capped divides and tapping the ancient river channels, receiving only the lower and richer stratum of gravel and then washing it, or, if cemented, crushing it under light stamps. In some places shafts 70 or 80 feet deep are sunk, and the lower gravel near bed rock is breasted out, hoisted, and washed. The larger drift mines are usually opened by tunnels.[1]

A quarter of a century ago the gravel was shoveled into hand cars and wheeled out to the mouth of the tunnel.[2] Since that time the larger drift mines in following the gravel channel have continued to extend their tunnels until they are miles in length.

To-day the gravel is removed by trains of cars operated by compressed air or electricity, the power being generated by the water flowing from the tunnels. The tunnels and drifts are lighted by electricity. A material saving in cost is made by the use of these compressed air or electric power plants. The loaded cars run out on the grade, and the power is used for hauling them back to the breasts at or near the foot of the tunnel. The natural drainage of the mines furnishes the power for haulage, lighting, and ventilating.[3]

The latest invention, one which promises to revolutionize the conditions of placer mining, is the dredge. It originated in New Zealand toward the end of the eighties, and after a few years' successful operation in that country was introduced in the United States and is fast gaining ground here. The great advantage of the dredge is that it is not dependent upon a large supply of water, but may be operated miles away from any stream, in the midst of orchard lands. No ditches or reservoirs are necessary, nor need there be a grade or fall for dump. Ground which has lacked suitable fall or water supply may now be mined by means of dredges. The working of these machines is thus described by Mr. Charles G. Yale in a report to the Director of the Mint on gold mining in California:

A pit or hole is dug at any likely point, in which is built or launched a hull or scow, on which the dredging machinery is placed. The ordinary surface water soon floats the dredge, which then commences operations. The great endless-chain buckets elevate the gravel and earth, which pass through "grizzlies" to separate the rocks and stones and earth. The rocks are carried by elevating apparatus far to the rear of the dredge, while the auriferous material passes through the gold-saving appliances, and the tailings or refuse pass out over the stream. The dredge keeps cutting a new basin for itself to float in as it digs away the bank ahead of it. Of course, the orchard soon disappears under this system, but the underlying gold in the gravel is worth far more than the trees and their product.[4]

[1] Report of the Director of the Mint on the Production of the Precious Metals, 1901, pages 90, 91.
[2] Tenth Census, Vol. XIII, Report on Precious Metals, page 203.
[3] Report of the Director of the Mint on the Production of the Precious Metals, 1901, page 91.
[4] Ibid., 1899, page 87.

The drawing on Plate I shows a California gold dredge which is driven by electric power and raises 150 cubic yards per hour from a depth of 30 feet below water level. The cost of such a machine is from $50,000 to $75,000, which places it beyond the reach of the small placer miner. Large tracts of auriferous ground heretofore lying idle have been bought up to be operated by dredging.[5]

Deep mines (See Plates II and III).—Quartz or deep mining developed naturally from alluvial or placer mining. When the deposits in the beds of the streams or higher up the flanks of the hill were exhausted, the miners followed the lines of the mineral yielding gold and finally came to the mother veins. The beginning of quartz mining also belongs to the Spanish and Portuguese period in the history of this continent. At first the method was merely an adaptation of the processes of alluvial mining. The gold deposit was laid bare by an open cut and worked as nearly as possible like a placer mine. The following description of one of these open mines is quoted from an account of a visit made by Mr. Dawson, secretary of the United States legation at Brazil, to the gold mining region of the state of Minas Geraes:

In Brazil these (the veins) are often of friable material, which can easily be pulverized with the aid of running water, and the country rock on either side of the vein is also frequently of the same character. Where such veins were found, we encountered the ancient open mines that are so characteristic of Brazilian gold mining. It is evident that the old miners knew nothing of the underground mining, and, except in rare instances, their excavations are open to the top. These great gullies were made with the assistance of running water brought from considerable distances in canals carried along a high level of the mountain flank. The water was conducted to the point where the lower outcrop of the vein began, and as it flowed, with the aid of a pick and shovel, the ore and surrounding material were cut away. This process was continued backward up the hill until the gully became so deep that the débris was unmanageable. The extent of some of these excavations is enormous. One at São João da Chapada, a few miles south of Diamantina, is 150 feet deep, 1,000 feet wide, and 2,000 feet long.

The mass of material washed down was concentrated in the rudest conceivable manner. Even the use of the sluice was not understood, and in its place the gravel was given its first wash in a "canoa." This is merely a level section of the canal in which the gravel and débris is carried down. The water is allowed to fall into this level space over a lip a few inches high, and a workman stirs with a sort of rake the gravel at that point. Below the "canoa" there is an inclined plane covered with hides laid with the hair up in order to catch the gold that does not sink to the bottom. In addition to the loss of gold inevitable with such a system of washing, the miners labored under the disadvantage of being liable to lose their vein by the falling in of the side rock. And not only did they lose the clue, but it is lost forever. Many of these old mines are undoubtedly still rich, but the veins are so covered up by the débris that their outcrops can not be found and traced. An interesting feature of the larger hillside mines are the "mondeas," rectangular masonry reservoirs, 50 to 80 feet square and 10 to 20 feet deep, made to catch and hold material washed down by the canal until it could be conveniently worked. They were necessary where the amount of water was large. In the few instances where the old miners exploited veins for which no

[5] Report of the Director of the Mint on the Production of the Precious Metals, 1901, pages 91 and 92.

water was available, they simply dug a hole, open to the sky, carrying out the mineral and earth upon the heads of slaves.[1]

Another writer says of their methods of quartz mining:

Quartz mines were only touched where they were found extremely rich, or in a state of decomposition that rendered them easily worked. Explosives were too expensive and difficult to obtain. The mode of working hard quartz was to heat it with fires and then pour cold water upon it, crack it, pry out the pieces, powder it up by hand, and then wash it.[2]

Gold mining in this primitive fashion was possible only with cheap slave labor. "Not the slightest improvement or advance was made as the years went by," says another observer. "The ruins of an abandoned working in Minas Geraes resemble exactly those of the Old World—in Spain, for example, which was to Rome and Carthage what California is to us to-day."[3] The same is true of the silver mines of Peru and Bolivia. "Until a short time ago all ores and all the water had to be carried from the mines on the backs of the workmen in leather bags."[4]

It goes without saying that the absence of mechanical apparatus for hoisting and pumping did not permit of vein mining except at very shallow depths.

In the United States the pioneer state in vein mining was Georgia, where a few deep mines were operated in the first half of the nineteenth century. The first miners naturally followed the methods which were in vogue in the Latin-American countries, whose experience extended over nearly three centuries. It is learned from a recent description that as late as the close of the nineteenth century a specimen of an open mine not very different from its Brazilian prototype was in actual operation in Georgia.

Where saprolite deposits are being worked by open cut, pipe lines are run from the water supply to the reservoirs or to hydraulic giants in the cuts. While the reservoir is being filled from the pumphouse, men are set to work in the open cut, with picks, to dig out the soft auriferous saprolite, and to break up any large masses of quartz that may be encountered, leaving the material where the waters will have free access to it. One of their number then goes up to the reservoir and opens the gate, when the water pours out in torrents down over the loosened saprolite, mixing with it till it forms a thick, slimy mud of the consistency of fresh mortar. This is gradually thinned down by the rushing waters, and is carried, with the angular blocks of quartz and harder saprolite, through the flume to the mill. The water, heavily charged with solid matter, rushes down the flume, through the sluices, and into the ore bin in the mill, where it deposits the coarser material, such as sand and blocks of saprolite and quartz, while the muddy water, containing a large part of the gold, passes through the racks, out of the mill, and into the nearest stream. The material which has been left in the ore bin is fed, by hand, into the stamp mill, and the gold is caught on the amalgamated copper plates, which vary in length from 4 to 12 feet. Short riffle boxes, containing mercury, are placed in connection with these plates, at their lower end, to catch such of the gold as may pass, with the tailings, over the plates; though it is known to be true that gold coated by lumonite ("rusty gold") will not amalgamate, and such of it as is not caught by the riffles must be lost.

One can not repress astonishment that so wasteful a system could have been in use for so long a time, especially as the ores are, for the most part, of low grade, though it is argued in its favor that this method of mining the saprolites carries with it the minimum of expense. While some of the gold, liberated by the disintegration of the auriferous saprolite by the waters, is caught up by the riffles in the sluices, and some finds lodgment in the ore pile in the mill house, still it is said, and is currently believed, that from 25 to 50 per cent of it is lost, being held by the solid matter in the swiftly running waters, eventually passing through the racks of the ore bin and out of the mill house before it is deposited. I am reliably informed that gold passing through the Preacher mill in this way is found all along the bed of the Tanyard branch, from the mill to the creek, a distance of 1 mile.[5]

In the early days of quartz mining in the United States the veins were worked to shallow depths only. In New Mexico about forty years ago powder was practically unknown in mining, and the veins could not be worked for more than 50 feet in depth.[6] Water was another source of trouble. Mines were operated by men of small means, capital was scarce, hand pumps only could be afforded, and when the column of water in the pump became too heavy to be lifted by hand, shafts with a good average grade of ore had to be abandoned. A recent example of this character is cited in the Report of the Geological Survey of Georgia, where but a few years ago a mine was abandoned upon reaching the depth of 300 feet, 30 feet below water level, because the operators had to lift with a hand pump an 80-foot column of water in order to keep the shaft free. At the time work ceased the ore was yielding $25 per ton.[7] The progress in the course of the last half century consisted in the introduction of more powerful hoisting and pumping machinery, in the invention of power drills and more effective explosives, in the construction of extensive tunnels for draining the mines, and lately in the application of electric power.

The evolution of mining methods and machinery is best exemplified by the history of the famous Comstock lode in Nevada. The greatest depth reached after more than twenty years of operation was 3,300 feet. In 1886 work in the lower levels had to be abandoned because of the overpowering flow of water. An instructive description of the powerful pumping plants which were in use at that time is given by Mr. R. K. Colcord, assayer of the United States Mint at Carson City, Nevada:[8]

The pump of the Union shaft works at the north end of the lode. Still there was what is generally known as a direct-acting double line of Cornish pumps with 10-foot stroke, driven by a compound

engine within inclined cylinders and inverted walking beam. The initial cylinder is 64 inches in diameter, with 6 foot 9 inch stroke, and the low-pressure cylinder is 100 inches in diameter, with 8 foot 6 inch stroke. The fly wheel is 36 feet in diameter and weighs 208,700 pounds. The wrought-iron walking beam is 22 feet long and weighs 238,610 pounds.

The pump rod is 18 by 18 inch Oregon pine, 2,618 feet in length, and its total weight in motion was 1,620,500 pounds; capacity about 750 gallons per minute to a height of 1,180 feet. This pump was started in 1880 and did good work, but was very expensive in its operation. The whole plant complete cost over $1,000,000.

The Yellow Jacket mine, Gold Hill, had a double line of 14-inch pumps with 10-foot stroke, driven by a horizontal compound engine with double box castings, 64 feet long for the bedplate. The initial cylinder was 31 inches in diameter, with 12-foot stroke, and the low pressure 62 inches in diameter, with 12-foot stroke. The pump rod was 3,055 feet long and weighs, when in motion, 1,510,400 pounds. Its greatest capacity was raising 750 gallons of water 1,516 feet per minute.

The pumps of the combination shaft of the Chollar-Norcross-Savage mining companies, 3,200 feet deep, consisted of a 14-inch Cornish pump and a hydraulic pumping plant, the first on the Comstock. This was operated by waterpower furnished by the Virginia and Gold Hill Water Company and discharged into the Sutro Tunnel. About the time deepest mining was discontinued and the mines allowed to fill and become permanently submerged, which was in October, 1886, this hydraulic system was lifting 2,138 gallons per minute a distance of 1,620 feet to the tunnel level. The total cost of this pumping arrangement was over $1,000,000.

At the date mentioned that hydraulic pump had all the water it could possibly handle. The Hale and Norcross 3,200-foot level had come to a connection with the combination shaft, also the Savage and the Chollar, was drifting south from the shaft on the same level. But the Chollar, drifting toward the already submerged mines of Gold Hill, encountered a constant increase of water—more than the hydraulic pump could manage. The water gained upon the shaftmen, and the result was that as no increase of pump power was feasible all had to submit to the inevitable and allow the hot water to have full submerging sway henceforth.

Recent improvements in electrical engineering and reduction processes have led to the resumption of mining on the levels which had been submerged for many years. Says Mr. Colcord:

The ponderous and powerful hoisting and pumping steam machinery plants of the chief mining companies, originally costing $500,000, $750,000, or more apiece, have become dismantled, and electric, up-to-date machinery of greater power and efficiency is being substituted and installed in their place at comparatively a mere trifle of their original cost. For instance, the electric-hoist plant of the Union Consolidated mine cost only about $10,000; Yellow Jacket and Belcher, $12,000 each; and that at the C and C shaft of the Consolidated California and Virginia, the most productive mine of the lode, $16,000. The cost of power furnished, as per contract with the Truckee River General Electric Company, is $7 per horsepower, based upon a continuous service and a two-minute peak load. In cases of such continuous service this shows an actual saving of 66 per cent. That is, the former rate for steam power was never less than $21 per horsepower.

Technical progress has been facilitated by modern methods of business organization. The pumping association formed for the purpose of pumping the water from the mines of the Leadville basin may be cited by way of illustration.

This association includes nearly all the leasing companies, as well as the owners of territory embraced in the Leadville basin. All mines operating within the association territory bear the cost of pumping in proportion to their output, based on net smelter returns less cost of hauling. By means of counters on these pumps the amount pumped is computed in gallons and charged to the association at the rate of 10 cents per 1,000 gallons. Those mines which pump are credited with the amount of water they have raised. Taking the entire district, investigation shows that the flow of water which must be handled is not less than 15,000,000 gallons a day. Comparing this amount of water with the average daily tonnage of the district for the past year, we find that 28.6 tons of water are raised for every ton of ore raised. Careful estimates of the cost of pumping have been compiled and show that it costs 4 cents to pump each ton of water to the surface. Hence, the cost of pumping referred to the ore makes a charge of $1.14 per ton extracted.[1]

Reduction of ores.—The extraction of the metals from the ore was in the early period not differentiated from mining. The most natural method which suggested itself to the human mind for dealing with the gold bearing rock was to reduce it to the same state in which the alluvial gold deposits were found and to separate the disseminated particles of gold from the pulverized mass by the familiar method of washing. These primitive methods are still practiced in the uplands of Mexico. Mr. Robert Hill, an American engineer, who examined some of the auriferous deposits in the state of Sonora, thus relates his observations in a village some 60 miles distant from a railroad station:

From the adjacent hills the quartz ore was brought in sacks on burros. This was placed upon a flat stone and pulverized with large round bowlders by small boys, this being apparently the first progenitor of the modern stamp mill. The pulverized material was then placed in a primitive arrastra, ground for thirty days by a perambulating burro, and amalgamated. This industry, so the urbane proprietor informed me, had been carried on by himself and ancestors for many generations, and from the ruins of the arrastras in the neighborhood and local tradition there is little doubt that gold has been mined here in a primitive fashion since the first invasion of Sonora by the Spaniards, in 1530, and probably prior to that time by the people who previously inhabited it. From this place onward we found the country inhabited entirely by the peasant class, whose only means of livelihood was to proceed to the hills when in need and procure a little gold with which to purchase the commodities of life.[2]

Amalgamation was the most important discovery inherited by the American miner from his predecessors. Survivals of the most primitive methods of reduction were recorded by the present census of mines and quarries. In a few cases the ore was crushed in ordinary mortars. At one mine in Maryland the ore, after being crushed in a mortar, was smelted in the neighboring blacksmith shop.

A type of mill generally used in the West in the early days of quartz mining was the Mexican arrastra. As late as 1880 arrastras still outnumbered the stamp mills.[3]

The arrastra in its simplest form consists of a circular bed of rock from 6 to 10 feet in diameter, with walls of vertical planks, having

an upright pivoted post in the center, from which extend 2 or 4 horizontal arms. Stone drags, weighing usually from 200 to 1,000 pounds each, are attached by ropes or chains to the extremities of the arms, and are slowly drawn around by the rotation of the latter. The depth is usually between 18 and 30 inches. The pavement and drags are of the hardest rock conveniently obtainable. * * * One man per shift can take care of two arrastras. Some waterpower arrastras working on tailings are so arranged that the only attendance needed is in feeding and discharging them, so that practically the labor required is less than the constant work of one man. Continuous arrastras receive no attention other than that demanded for repairs. The smaller arrastras are worked by a single mule or horse. When waterpower is obtainable, a small overshot hurdy-gurdy, or turbine wheel, is employed.[1]

The capacity of an arrastra does not exceed 4 tons per day of twenty-four hours, and usually varies from 1 to 2 tons. A crude arrastra operated by mule power can be built for $150, which places it within the means of miners with but small capital. The owner often does all the work.

Wooden stamp mills of a very crude type were also known to the Spanish-American miners. A quaint specimen of a homemade stamp mill, fairly representative of its Spanish prototype, was seen at work a few years ago in Georgia. The mine and the mill were worked a few months in the year by the owner, with the aid of his aged mother.

The son packed selected ore in a bag on his back to a rude mill a quarter of a mile from the shafts and emptied it into a nail keg. The mother fed the mill with a shingle. Working thus from sunrise to sunset they eked out a living, never making less than $1 a day apiece. The stamp mill has been accepted by all who have seen it as the first of its kind. A 10-foot overshot water wheel, with axis elongated at one side, set in propped posts, constitutes the motor. Three spindles, roughly hewn, are shod with radially arranged and overlapping bands of iron (pieces of a wheel tire) bound by a ring. These are the stamps. The mortar consists of the remnant of the shoe material. Flat iron plugs, bent at the end, are so arranged in the axis that when it revolves these plugs catch, lift, and drop each notched spindle at different intervals. The screen of the mortar chamber is a piece of iron stovepipe rolled out and punctured with nail holes. A combination sluice box does the rest.[2]

This mill was imitated by other miners in the same and neighboring counties. The cost of construction of a first-class mill of this type did not exceed $100. From the wooden mill, by gradual improvement, the present iron stamp mill, with steel shoes and mortars, was developed. The modern stamp milling process is described as follows:

Gold stamp milling is that particular process in which a heavy cylindrical body is made to fall upon the ore in such a manner as to crush it, and thereby facilitate a separation between the gold and the valueless minerals by which the gold is incased. The latter weigh less than the former, and are removed by the aid of water. The gold is then collected through the agency of mercury, with which it readily forms an alloy or amalgam. From this combination it is finally extracted by the distillation or retorting of the mercury. The mechanism of the stamp acts on principles similar to those underlying the crudest devices used by man. It may be likened to a hammer, of which the shoe is the hammer head, the stamp stem is the handle, and the die is the anvil. The ore itself has been compared to a nut struck by a hammer, whose blow has separated the valueless shell (the quartz) from the valuable kernel (the gold). Water covers the die and the ore lying upon it. The blow of the falling stamp not only crushes the ore, but also causes a violent pulsation of the water. That pulsation becomes converted into an irregular splash against the sides of the mortar. The latter has an opening in front, through which the water is discharged, carrying with it the crushed ore. This, called the "pulp," spreads itself over tables placed on an incline, which are lined with a metal, usually copper, having an amalgamated surface, such as will arrest the particles of gold and at the same time permit the grains of quartz and other valueless material to pass over it and out of the mill.[3]

With the further progress of gold mining a point was reached where the stamp mill was found inadequate. After the gold bearing veins had been worked to a certain depth, usually a few hundred feet below the surface, the gold would cease to be "free milling" and, because of the lack of those changes which are due to the penetration of water from the surface, would become "refractory," that is, locked up in union with iron pyrite and other materials, so that it would not amalgamate with quicksilver.[4] Many mines were abandoned when the free milling ores gave out. In Gilpin county, Colo., this condition was met with very early in its mining history, at levels varying from 100 to 200 feet.

The mills which had previously been extracting from 60 per cent to 70 per cent of the gold contents gradually commenced to return only 50 per cent, 40 per cent, and then 30 per cent. None but the richest ore would now pay; the mills swallowed up two-thirds of the yield which should have rewarded the miner's toil; some of the mines were forced to shut down, while others had to confine their development to the narrower, richer portions of the lodes. * * * At this juncture a small smelting establishment was erected in the district, and the metallurgist came to the rescue of the baffled millman.[5]

The problem was not fully solved, however, until the eighties, when the process of concentration was introduced. Only rich ores could bear the expense of shipment to distant smelters. As a result, low-grade refractory ores which could not be treated by amalgamation were thrown away. The new process of concentration, which reduced the volume of ore to be shipped and treated, was tantamount to a discovery of new gold mines.

An illustration of a modern stamp mill, equipped with a concentrator, is shown on Plate IV.

The following description of this process is condensed from the report of the Colorado bureau of mines:

The system of ore dressing known as concentration is one of the most important of all processes applied to the treatment of ores carrying low values in gold, silver, lead, and copper. There is probably no other line of ore dressing so universally used. Notwithstanding the new devices introduced, all are in line with the early and original designs, differing only in the manner of application of principles involved. The theory of concentration is based

upon the variable specific gravity of the different minerals. Its application is to separate the various metals, collect those having value, and reject the remainder. A large proportion of the concentrates marketed are derived from the stamp-mill tailings. When the value in tailings is in form of pyrite, chalcopyrite, and galena, with gold and silver associated, the ore passes direct from the plates to different patterns of oscillating, or bumping, tables, and the separation made. Where the base minerals occur in comparatively large crystals the stamp battery is often preceded by crusher, rolls, sizing screens, and hartz jigs, the jigs yielding a coarse concentrate, and the tailings from jigs being recrushed in battery over the plates and tables.[1]

The problem of an economical process for the treatment of low-grade ores for many years tempted the inventive spirit of mining men. Many processes were devised only to be rejected by experience. The "process man" became the object of cheap ridicule even in official publications. It was, however, owing to the efforts of one of the multitude of these "process men" that the cyaniding process was invented, which gave to the world the wealth of South African gold. At first the new process was met with distrust by practical mining men, but its demonstrated success overcame the doubts of the skeptics. Immense dumps of low-grade ore and tailings which had been accumulating since the beginning of mining operations were taken up and reduced by the new process.

It is estimated by Professor Munroe that in 1902 gold to the value of $8,000,000 was produced by the cyaniding process in the United States. This represents an addition of 13 per cent to the productivity of deep gold mines.

Improvement in the processes of extracting the metals from the ore is a potent factor in the development of mining. By the old amalgamation process not more than 70 per cent, and usually not more than 60 per cent, of the gold contents of the ore was saved. With the aid of modern processes more than 90 per cent of the assay contents can be recovered.

General industrial conditions.—The development of the railway system with consequent reduction in freight rates has greatly stimulated the growth of gold and silver mining. When mining operations first commenced in Arizona, some mines were 300 miles away from the nearest railroad, and machinery and supplies were brought in by mule teams.[2] Twenty years ago no mine could be worked there which produced ore worth less than $150 per ton.[3] In some mining districts of Colorado, as late as fifteen years ago, before they were reached by railways, all ores were subject to freight charges, varying from $50 to $100 per ton. These conditions are now largely a thing of the past. To-day, all important mining camps are crossed by spurs and switches connecting the principal mines with the main railway line. This means a saving of many dollars per ton on all ores shipped, besides a saving on coal and other mine supplies. The decrease of the average value of the ore per ton has been noted on a preceding page. In the light of present statistics the following quotation from a report published twenty years ago on silver mining in California is instructive:

> Only ores worth from $100 to $200 are sent to mills. Richer ores are sold in San Francisco or elsewhere, while the low-grade ores are dumped. Dumps are covered with a large quantity of ore, the greater portion of which is low grade, averaging from $40 to $60 to the ton.[4]

Silver ores averaging from $40 to $60 to the ton are to-day considered exceptionally rich.

The decline in the average grade of ore mined and treated must not be mistaken for an indication of what the economists call "diminishing returns." The dumping of a portion of the ore after it has been raised from the mine increases the average cost of mining per ton of ore treated. Since it has become possible to treat low-grade ores which formerly had to be thrown away, the returns have increased in proportion to the expense per ton of ore actually raised, there being no additional cost of mining. Thus production has been cheapened.

The combined effect of all these advances in the processes of mining and reduction and in transportation has been the reopening of many mines which were abandoned years ago when the supply of the very rich choice ores had been exhausted. Says Mr. Yale, who has for many years been a close student of mining conditions in California:

> Along the mother lode the best paying mines of to-day, and the deepest, are those which had lain idle for many years, but were intelligently reopened and properly equipped with modern machinery. Capitalists seem to prefer to reopen a mine which had made a record for bullion output in its early history rather than to take the chances on opening and developing an entirely new prospect. Several of the most productive mines at the present day are those which were abandoned twenty or thirty years ago, at a depth of 400 or 500 feet, when it was thought there was nothing worth seeking for further down. On the reopening of these mines, however, systematic deep sinking was carried on, since which time they have been much more profitable than during their early career.[5]

The introduction of improved machinery and reduction methods calls for a large investment of capital. The effect of the technical progress has therefore been the gradual displacement of the small operator working his mine without hired labor on the "grub-stake" plan, and the concentration of gold and silver mining under the management of large companies. The general trend toward production on a large scale has already been noted. The movement toward combination, however, has as yet not reached the gold and silver mines. Small properties have here and there been combined into larger ones; still these small aggregations in no way differ from ordinary incorporated companies and lack the magnitude which is characteristic of a modern industrial combination. In the reduction of ores, on the other hand, combination has made considerable progress.

TABLE 91.—DETAILED SUMMARY, MINES REPORTING

		United States.	Alabama.	Arizona.	California.	Colorado.	Georgia.
1	Number of mines	3,252	3	380	389	955	8
2	Number of operators	3,252	3	380	389	955	8
	Character of ownership:						
3	Individual	683	2	74	111	237	3
4	Firm	849		95	131	282	3
5	Incorporated company	1,695	1	207	146	433	2
6	Other form	25		4	1	3	
	Salaried officials, clerks, etc.:						
7	Total number	2,284	4	385	259	449	6
8	Total salaries	$2,335,470	$3,100	$458,372	$264,575	$434,888	$8,568
	General officers—						
9	Number	302		32	22	64	3
10	Salaries	$242,989		$44,396	$12,995	$42,641	$4,800
	Superintendents, managers, foremen, surveyors, etc.—						
11	Number	1,307	3	253	167	271	2
12	Salaries	$1,523,627	$2,200	$333,944	$188,552	$299,155	$3,600
	Foremen below ground—						
13	Number	430		38	41	77	1
14	Salaries	$410,185		$43,611	$36,698	$71,034	$168
	Clerks—						
15	Number	245	1	62	29	37	
16	Salaries	$158,669	$900	$36,421	$26,330	$22,058	
	Wage-earners:						
17	Aggregate average number	11,763	7	2,243	1,447	2,303	29
18	Aggregate wages	$11,580,684	$2,644	$2,326,885	$1,311,152	$2,314,208	$11,552
	Above ground—						
19	Total average number	2,845	6	604	405	488	9
20	Total wages	$2,782,876	$2,332	$637,741	$359,718	$525,254	$3,563
	Engineers, firemen, and other mechanics—						
21	Average number	1,572	2	308	189	350	3
22	Wages	$1,766,784	$960	$389,446	$190,459	$396,198	$1,200
	Miners—						
23	Average number	312	1	53	75	29	
24	Wages	$235,955	$463	$40,545	$62,341	$25,138	
	Boys under 16 years—						
25	Average number	5		2			
26	Wages	$1,100		$480			
	All other wage-earners—						
27	Average number	956	3	241	141	109	6
28	Wages	$779,037	$909	$207,270	$106,918	$103,918	$2,363
	Below ground—						
29	Total average number	8,918	1	1,639	1,042	1,815	20
30	Total wages	$8,797,808	$312	$1,689,144	$951,434	$1,788,954	$7,989
	Miners—						
31	Average number	8,019		1,506	909	1,662	20
32	Wages	$8,057,301		$1,567,580	$846,810	$1,634,154	$7,989
	Miners' helpers—						
33	Average number	571		67	79	61	
34	Wages	$456,292		$63,475	$59,700	$63,256	
	Boys under 16 years—						
35	Average number	1					
36	Wages	$450					
	All other wage-earners—						
37	Average number	327	1	66	54	92	
38	Wages	$283,765	$312	$58,089	$44,924	$91,544

PRECIOUS METALS RECOVERED BY CYANIDE PROCESSES

PRECIOUS METALS RECOVERED BY CYANIDE PROCESSES.

By Charles E. Munroe, Ph. D.

The returns for 1902 show that during that year there were 109 establishments, in 12 different states, using a cyanide process for the extraction of the precious metals from tailings or ores. Of these establishments, 29 cyanided the ore or tailings without other treatment; 27 crushed the ore previous to cyaniding; 5 concentrated the ore; 20 combined amalgamation for coarse gold with cyaniding for the finely divided gold; 18 combined concentration and amalgamation with cyaniding; 6 combined smelting, and in some instances amalgamation with cyaniding; and 4 combined chlorination, with and without amalgamation, with cyaniding. During the census year these establishments treated 3,089,673 tons of ore and 199,689 tons of old tailings, or 3,289,362 tons in all, and produced 776,050 fine ounces of gold, valued at $15,972,268, and 1,741,546 fine ounces of silver, valued at $871,878; the products included also 15,000 pounds of copper, valued at $1,670; 741,000 pounds of lead, valued at $12,494; and 8,726 pounds of mercury (recovered from tailings), valued at $5,620, so that the total value of all the products was $16,863,930.

The returns showed directly that of the total output of precious metals 289,305 ounces of gold, valued at $5,947,888, and 560,872 ounces of silver, valued at $287,614, were extracted from 1,156,643 tons of ore and tailings by means of some cyanide process of recovery. It is estimated that in those operations in which amalgamation, chlorination, smelting, or several of these processes were combined with a cyanide process, gold to the value of $2,000,000 and silver to the value of more than $300,000 were recovered by cyanide processes. Hence, by the use of such processes there were produced in the United States, in 1902, gold with an estimated value of about $8,000,000, and silver with an estimated value of about $600,000.

A detailed summary for cyaniding mills is presented in the report on gold and silver.

OCCURRENCE OF GOLD.

Gold, when found *in situ*, is generally in quartz veins intersecting metamorphic rocks, and to some extent in the wall rock adjoining these veins. It may occur either free or combined apparently with tellurium and perhaps selenium, and it is associated with pyrite (iron disulphide), chalcopyrite (copper-iron sulphide), galena (lead sulphide), sphalerite (zinc sulphide), mispickel (iron sulph-arsenide), and many other minerals containing sulphur, antimony, bismuth, cobalt, nickel, the platinum group of metals, etc. On exposure to the atmosphere these minerals may undergo chemical changes, whereby many of their constituents are converted into other compounds, while the metallic gold is set free. Atmospheric action also breaks the veinstone into fragments, which are ground to smaller particles by attrition. When suspended in flowing water the superior density of the gold causes the particles, together with the heavier particles of the vein matter, to settle out, through a natural concentrating action, in an obstructed portion of the stream, forming alluvial deposits or placers. Through geologic changes such alluvial deposits may again be formed into rock masses, the gold being found in conglomerate rock cemented together by finely divided material, which may be barren or may itself contain gold. When the gold occurs free in quartz or in a weathered vein, it is called a free-milling ore; when it is intimately associated with sulphurets and similar substances, it is called a refractory ore.

Free gold, as found in nature, is never pure, being alloyed to a greater or less degree with silver, copper, and other metals. It occurs in quartz in the form of strings, scales, or plates, and at times in considerable masses of aggregated crystals; the scales are often so small as to be invisible to the naked eye, so that quartz

showing no "color" and no evidence of gold on panning may yet yield a considerable percentage on assay. The metal is very irregularly distributed through the quartz, being disseminated throughout its mass, and also occurring in cavities; it is in these cavities that the largest masses and most perfect crystals of gold are found. Alluvial gold occurs usually in flattened scales of different degrees of fineness, the size and shape depending partly on its original condition in place, and partly on the amount of attrition it has undergone in transport. The average fineness of the gold in a placer is determined by the assorting action of the running water that transported the materials from their point of origin; the coarser particles, requiring rapid currents to transport them, are dropped first, while the finer particles are carried long distances, sometimes scores of miles. Another agent which has borne no inconsiderable part in this transportation, delivering its burden to the streams at its base, is the glacier.

MINING AND RECOVERY OF GOLD.

Placers.—In the earlier operations in auriferous districts, the gold is obtained from the placers by the use of the pan, rocker bumper, "long tom," and sluice, and by hydraulicking. The hydraulic process was employed by the Romans, but it has probably reached its greatest development in this country, since its introduction in California in 1853. In this process, as in the workings of nature, the energy of a head of water dislodges the gold bearing detritus, and the buoying power of water at different rates of flow separates the heavier from the lighter particles. Even in ancient times, these methods were often supplemented by the use of mercury, either in the liquid state or exposed on plates, to catch and retain, by amalgamating with them, the lighter particles of gold, which would otherwise flow away with the dirt. More recently, dredging has been resorted to in order to recover the gold bearing alluvium from river beds, and even from deposits in former river beds, over which have since formed deposits of silt so deep that the water has been turned from its course.

Free milling ores.—When the placers have been exhausted, attention is given to the recovery of the gold *in situ* by vein or quartz mining. As long as the ore is free milling, the process consists in detaching it from the vein by drilling and blasting. It is then crushed by stamps, crushers, or rock breakers, and treated, like placer deposits, by sedimentation and amalgamation. The machinery and devices used for concentration, separation, and amalgamation have been very highly developed, especially during the past century. During the last half century treatment by chlorine has been resorted to for the recovery of the fine gold.

Refractory ores—old methods.—When refractory ores are reached, the methods of mining are changed. Before the introduction of the cyanide process, the gold in these ores was extracted by smelting, chlorination, or other elaborate chemical process, the degree of success depending on the richness of the ore in precious metals or in other materials that would yield a profit on the operations. Thus the precious metals associated with galena were alloyed with the lead reduced from it by smelting, and subsequently recovered by processes such as that of Parkes or Pattison; iron pyrites carrying the precious metals were roasted to convert their sulphur content into sulphuric acid, and the precious metals were then recovered from the pyrite cinder, and these methods are still employed. Copper pyrites, which usually carries gold and silver, and has long been a source from which these metals were obtained, has become a notable source of supply, since the development of Manké's method of bessemerizing copper mattes and the successful refining of this impure copper by electricity. These are a few among numerous methods proposed or used for the treatment of refractory ores. In the development of the milling processes it has become possible to assort the ore into different concentrates, each of which is treated by that process which will most effectively and economically extract the gold and other valuable substances present.

On account of the cost of transportation or treatment, however, at many mines only the most valuable of the ores could be worked profitably; moreover, after the greatest possible value had been extracted by concentration or by some other comparatively crude form of treatment, the tailings—carrying with them, in the aggregate, much gold and silver—were disposed of as inexpensively as possible. Thus, in the early days of the Comstock lode in Nevada, which has yielded gold and silver valued at more than $400,000,000,[1] the treatment of the ores was limited to mill batteries, amalgamating pans, and settlers, the tailings—still containing notable quantities of the precious metals—being deposited in the canyons leading to the Carson river. Later, blanket sluices, riffles, and other devices were employed to catch the rich sulphurets that had escaped previous treatment, as well as quicksilver and amalgam from the plates; in addition, restraining dams and reservoirs were constructed at favorable points in the two canyons, and along the edges of the river, to catch the tailings and the rich chloride slums or settlings, but both the dams and their accumulations were sometimes swept away by winter floods. Since the erection, in recent years, of several cyanide plants at Silver City and Six Mile Canyon to work these tailings, it has been estimated, on the basis of the values recovered from the tonnage work, that the value of the precious metals swept into the river and spread over its erratic bed and sandy flats aggregated $60,000,000. This estimate is supported by the results obtained in attempting to recover some of these values from the river bed by dredging and other means.

[1] Report of the Director of the Mint upon the Production of the Precious Metals during 1902, page 158.

All of the long-used methods have been open to criticism with regard to efficiency or economy. Thus, in the working of placers or free milling ores, sometimes the finest particles of gold were not precipitated by the riffle bars or caught on the blankets, but floated away with the slimes; again, the grains of gold were often "rusty," or so coated as to refuse to amalgamate when brought in contact with the mercury, and hence, in spite of the use of metallic sodium, or of potassium cyanide and other chemicals, much gold escaped; or the presence of lead, copper, arsenic, antimony, or other substances in the ore caused the mercury to become "foul," and therefore unable to take up gold. These, combined with other causes of loss, have led to the estimate that although gold to a value of over $1,000,000,000 has been produced in California since 1848, "yet more has been wasted in milling and hydraulic mining by being washed down the rivers and even to the ocean."

Such were the conditions that existed in 1888, when, by tests made on a large scale, it was demonstrated that the cyanide process for the recovery of gold and silver from low-grade ores was of practical value and low cost, making it possible to work profitably the large bodies of low-grade ore scattered over the earth, and the enormous piles of tailings accumulated around both abandoned and active mines and mills and being continually added to as mining and milling proceeded.

THE CYANIDE PROCESS.

History.—According to Hoefer,[1] prussic acid appears to have been known to the Egyptian priests, who used it for poisoning initiates guilty of divulging the sacred mysteries. According to Eissler,[2] the fact that gold when in a fine state of division was soluble in cyanide of potassium was already known in the Middle Ages, when the gilding of metals was carried out by jewelers and alchemists by the use of gold in cyanide solutions. Unless potassium cyanide was at that time made from prussic acid obtained from vegetable sources, it is difficult to reconcile this with the statements made by Watts, by Roscoe and Schorlemmer, and other authorities, that potassium ferrocyanide was discovered by Macquer in 1752 and hydrogen cyanide by Scheele in 1782; for these, particularly the former, are the present sources of potassium cyanide. It has long been known, however, that in the kernels of the bitter almond, peach, apricot, plum, cherry, and quince, in the blossoms of the peach, sloe, and mountain ash, in the leaves of the peach, cherry laurel, and Portugal laurel, in the young branches of the peach, in the stem bark of the Portugal laurel and mountain ash, and in the roots of the mountain ash, there occur certain glucosides which, through the action of an enzyme in the presence of water, become hydrolyzed, yielding hydrogen cyanide, or prussic acid, as one of the products.

[1] Histoire de Chemie, Vol. I, page 226.
[2] The Metallurgy of Gold, 1896, page 378.

The solubility of gold and silver compounds in cyanide solutions was demonstrated by Scheele on pages 405 and 406 of his chemical essays. According to Gore,[3] it was the reading of this passage in Scheele's work which in 1840 suggested to John Wright, of Birmingham, England, the suitability of cyanides of gold and silver, dissolved in solutions of alkaline cyanides, for use in electroplating. This plan was immediately tested with solutions of silver, first in potassium ferrocyanide and later in potassium cyanide, and the results were so successful that this method of electroplating was embodied in a British patent issued to G. R. and H. Elkington, March 25, 1840. This patent became the basis of the arts of electro-silvering and electro-gilding which have been so extensively practiced ever since. It was in 1840, also, that the solubility of the metals themselves was taken advantage of, for in Mason's "separate battery," devised in that year, the necessity of supplying additional metallic salt to the bath as the deposition went on was obviated by the use of an anode composed of the metal to be deposited on the object suspended at the cathode.

In "The Cyanide Process, its Practical Application and Economical Results,"[4] Scheidel says:

> The first record, in scientific literature, of experiments in which metallic gold was dissolved in a cyanide of potassium solution consists in Prince Pierre Bagration's paper in the Bulletin de l'Academie Imperiale des Sciences de St. Petersbourg, 1843, tome 11, page 136. Bagration, who alludes to Elkington's process, preserved cyanide of potassium solution in a dish gilded on the inside. He noticed that after eight days the whole gold surface had been attacked. He experimented then with finely divided gold under the influence of the galvanic current. The latter he soon recognized as not of any benefit in the dissolving process. He precipitated the gold out of the cyanide solution by means of the electric current on a cathode of copper. Continued experiments proved the advantage of higher temperature during the dissolving process, and taught the precipitation of gold from its still warm solution by means of silver or copper plates, without the electric current. The higher temperature had, however, the disadvantage of the silver and copper being strongly attacked by the cyanide solution during the precipitation process. Bagration extended his experiments to solutions of ferrocyanide, which he found to act like cyanide, but in a much less degree. He further studied the solubility of gold in the form of plates in cyanide and found it to be dissolved in such form at a considerable rate at a temperature of 30° to 40° C. He noticed the influence of the air on the reaction. Bagration believes that hydrocyanic acid in a state of generation is a gold solvent, and he concludes his paper with the remark that in the future cyanide of potassium must be enumerated among the solvents of gold. L. Elsner published in J. fr. Chem., 1844, page 441, his observations on the reactions of "reguline metals" in an aqueous solution of cyanide. He found that gold and silver were dissolved in potassium cyanide without decomposition of water. "The dissolution of the metals is, however, the consequence of the action of oxygen which, absorbed from the air, decomposes part of the cyanide." His reaction has been expressed by others in the following equation:

$$\underset{\text{(Gold.)}}{2\,Au} + \underset{\text{(Cyanide of potassium.)}}{4\,KCy} + \underset{\text{(Oxygen.)}}{O} + \underset{\text{(Water.)}}{H_2O} = \underset{\text{(Auro-potassic cyanide.)}}{2\,AuKCy_2} + \underset{\text{(Potassic hydrate.)}}{2\,KOH}$$

[3] The Art of Electro-metallurgy, 1877, pages 19 and 20.
[4] California State Mining Bureau, Bulletin No. 5, 1894, page 9.

It is generally called Elsner's equation. Some years after, Faraday made use of the solubility of gold in cyanide solution for reducing the thickness of gold films. (Experiments on the relations of gold and other metals to light, Transactions of the Philosophical Society, 1857, page 147.) The basis of the most modern process for the extraction of gold was thus provided.

In confirmation of Elsner's theory as to the action of oxygen, which has been disputed, it may be noted that V. Lehner has recently shown [1] that gold will dissolve in common acids, like sulphuric and phosphoric, if oxygen be present in the solution, and that the solubility of gold in selenic and telluric acids is due to the fact that at the temperature which obtains in the reaction these acids are themselves broken up into dioxides and oxygen.

The first instance of an attempt to apply this solvent action of the cyanides to the extraction of precious metals from their ores or other bodies containing them appears in United States Patents 61866 and 62776, issued to Dr. Julio H. Rae, of Syracuse, N. Y., on February 5 and March 12, 1867. Dr. Rae claimed the use not only of potassium cyanide as a solvent for the precious metals in the ore, but also of an electric current in precipitating them from the solution, and of rotatory or movable electrodes. This was followed by United States Patent 229586, of July 6, 1880, to Thomas C. Clark, of Oakland, Cal., who roasted his ore to a red heat, and placed it, in this condition, in a cold bath containing salt, prussiate of potash, and caustic soda; United States Patent 236424, of January 11, 1881, to H. W. Faucett, of St. Louis, Mo., who subjected hot crushed ores, under pressure, to the action of sodium cyanide in solution; and United States Patent 244080, of July 12, 1881, to John F. Sanders, of Ogden, Utah, who treated his ore with potassium cyanide and glacial phosphoric acid. But in each of these last three patents the object was to cleanse the gold previous to amalgamation, potassium cyanide having been used for a considerable time, in California and Australia, for removing the coatings from rusty gold in the pan amalgamation process.

In 1884 Astley P. Price applied for British Patent 5125, for the use of zinc in a state of fine division in precipitating gold or silver from solutions containing them. On July 28, 1885, United States Patent 323222 was issued to Jerome W. Simpson, of Newark, N. J., covering the extraction of gold, silver, and copper from their ores by means of solutions containing potassium cyanide, ammonium carbonate, and sodium chloride, and the subsequent precipitation of the dissolved metals by means of pieces or plates of zinc suspended in the solution. A caveat for the use of cyanide was filed in the United States Patent Office by F. M. Endlich and N. W. Mühlenberger, during the same year, but was subsequently abandoned. At Park City, Utah, about the same time, Louis Janin, jr., made experiments with cyanide in extracting silver and gold from ores, which led to his filing a caveat on May 1, 1886. He did not press this to an issue, but he published his results in the Engineering and Mining Journal, 1888.[2] W. A. Dixon also made experiments with cyanide on Australian ores, and recorded his results in a paper read before the Royal Society of New South Wales.

The cyanide process acquired commercial value in 1887, when John S. MacArthur and W. Forrest, of Glasgow, Scotland, applied, on October 19, for their English patent covering the use of dilute solutions of cyanides in the extraction of the precious metals. Later they obtained a patent for the use of zinc as a precipitant in a particular state of subdivision.

The commercial value of the cyanide process was demonstrated by tests made on a large scale, with ore from the New Zealand Crown mine, in June and July, 1888. Commercial success dates from the introduction of the MacArthur-Forrest process, in 1890, in the Witwatersrand gold fields in South Africa, the first cyanide plant in the world for treating tailings having been erected at Johannesburg in April, 1890.[3] In the Witwatersrand alone, at the end of 1891, there were 6 companies treating tailings by the cyanide process; at the end of 1892 there were 22; and at the end of 1893 there were 32, with a record of 143,500 tons per month treated. By the use of this process there were recovered in the Rand 286 ounces of gold in 1890, 34,862 ounces in 1891, 178,688 ounces in 1892, 330,510 ounces in 1893, 714,122 ounces in 1894, 753,490 ounces in 1895, and 703,704 ounces in 1896; the output then increased up to September, 1898, when the commencement of active hostilities in the Boer War interfered with the active working of the mines.

Methods.—The cyanide process consists in lixiviating the finely powdered ore with a dilute solution of an alkali cyanide, drawing off this solution when charged with the precious metals, and precipitating these metals from the solution. In the patents of MacArthur and Forrest the claims were made for the use of dilute solutions of cyanide (not more than 8 parts of cyanogen to 1,000 parts of water); the employment of caustic alkalies for neutralizing acid ores, prior to their digestion in the cyanide solution; and the use of zinc, preferably in a filiform condition, as a precipitant. The cyanide first used was potassium cyanide, but cyan-salt, which is a mixture of sodium and potassium cyanides, has come into extended use. The tailings, or a charge of ore crushed to the desired fineness, are placed in the leaching vats or tanks and, if acid, given a preliminary treatment with lime or sodium hydroxide, which is generally washed out before further treatment. The ore is then subjected to the action of the cyanide solution, which is usually admitted at the bottom of the leaching vat; after digesting for a length of time, depending on the

[1] Journal of the American Chemical Society, 1904, Vol. 26, pages 550 to 555.

[2] Page 548.

[3] Alfred James, Cyanide Practice, frontispiece, 1902.

character of the charge, its fineness, its freedom from slimes, and the strength of the cyanide solution, the solution containing the precious metals is drawn off and the operation repeated. According to Elsner's equation and the elaborate investigations of MacLaurin and Christy, the presence of oxygen in the solution is essential, hence many operators use sodium peroxide or other oxidizing agents with their cyanide solutions.

The leaching or percolation vats vary much in form, dimensions, and construction. Thus they may be of wood, barrel-shaped, 22.5 feet in diameter and 4 feet deep, and holding a charge of 30 tons; or of concrete, rectangular, 50 by 40 feet in area and 4 feet deep, and holding 150 tons.

The following facts from Packard's paper on "The Cyanide Process in the United States"[1] indicates the wide ranges of variation in methods:

In the Mercur district the ore is covered with solution, which is allowed to stand from thirty minutes to six hours and then drawn off. This operation is repeated from eight to thirty-five times. Here the material leached is so coarse that there is no danger of "packing." Each operation of covering takes from two to six hours. A few mills cover the pulp with solution, allow it to stand forty-eight to ninety-six hours, draw it off, and wash. Many of the mills follow the strong solution with a wash of weak solution (one-tenth per cent or less). This is in turn followed by a water wash, which flows through the zinc boxes into the weak solution tank and becomes the first wash for the next charge.

In the extraction processes referred to above the treatment with cyanide solutions is accomplished by percolation. This method is widely and successfully used, but it has its disadvantages. If the material treated is a clean sand, the solution penetrates throughout the mass, exerting its full solvent effect, and the subsequent draining and washing are easily accomplished. But if the ore contains some kind of rock which is converted by the crushing into a powder that when moistened produces slimes—a formation which is most marked when the rock is of a clayey nature—the presence of these ore slimes in the leaching vats may retard or even prevent percolation, according to their amount and character. In working ores of this kind, the difficulty has been obviated by coarse crushing, but in that case gold is lost, because the solvent can not penetrate through the coarser granules of ore to the inclosed grains of metal. To overcome these defects in the process, resort is had—as in the Pelatan-Clerici process, or in the use of the Aurex sluice—to agitation during exposure to the cyanide solution. Furthermore, since in these processes amalgamation and precipitation are carried on nearly simultaneously with solution, not only is the coarse gold quickly removed, but the rusty gold is made capable of amalgamation through being cleansed by the action of the cyanide and the electric current, which are employed simultaneously, while the float gold is either amalgamated directly or dissolved and then precipitated. In these processes the precious metals are recovered as amalgams, which need only retorting and melting to be ready for the mint.

A novel method of overcoming the impermeability of slimes is found in the suggestion of Count von Schwerin,[2] who proposes to remove water from wet clay and similar amorphous fine slimes by passing through the mass an electric current, whereby the water is driven to the cathode and the solid particles to the anode by "electric endosmosis." The apparatus consists of a wooden vat having for a bottom a brass netting, which forms the cathode; the water being drawn to the netting quickly runs off.

In the MacArthur-Forrest process, the cyanide solution containing the gold and silver is next run into zinc boxes for the precipitation of the precious metals. The zinc boxes, like the leaching vats, vary in character at the different works. A form in common use in the United States is made of 2-inch dressed plank, bolted together and painted with paraffin paint; it is divided into six compartments, 13 by 20 inches in cross section and 20 inches deep, and is provided with a screen about 4 inches above the bottom, on which to place the zinc shavings. About sixty pounds of shavings are required to fill the box. It is provided with an inlet and an outlet pipe, and in the bottom of each compartment is placed a 1-inch pipe closed with a stopcock, through which the slimes are drawn off in cleaning up. The circulation in the zinc box is secured by having the first partition of a compartment extend from the top of the box to within 3 inches of the bottom, while the second partition extends from the bottom of the box to within 2 inches of the top. The screen for the zinc shavings is stretched between. The solution from the entrance pipe falls to the bottom of the box, passes under the first partition, rises up through the zinc shavings, flows over the second partition, and thus proceeds up and down from compartment to compartment until it reaches the exit pipe of the box. The Mercur mill is equipped with long sheet-iron boxes having wooden partitions wedged into place; these can easily be removed for cleaning up, the slimes being all brushed together. At the Cripple Creek mill, the slime discharge pipes of the zinc boxes lead from the side of each compartment and discharge the slime into a trough leading to a tank.

When the potassium cyanide solution comes into contact with the gold in the leaching vat, the gold is dissolved, forming potassium aurocyanide, according to the following equation:

$$4\,KCy + 2\,Au + O + H_2O = 2\,KAuCy_2 + 2\,KHO.$$

[1] Transactions of the American Institute of Mining Engineers, Vol. XXVI, pages 709 to 721.

[2] Zeitschrift der Elektrochemie, 1903, page 739.

According to Christy,[1] when the solution of potassium aurocyanide, containing, as it usually does, an excess of potassium cyanide, is brought into contact with the zinc, the reaction may be represented by

$$2\ KAuCy_2 + 3\ Zn + 4\ KCy + 2\ H_2O = 2\ (ZnCy_2\ .\ 2\ KCy) + K_2O_2Zn + 2\ H_2 + 2\ Au;$$

but in the absence of free potassium cyanide the successive reactions taking place may be summed up in the following equation:

$$4\ KAuCy_2 + 4\ Zn + 2\ H_2O = 2\ ZnCy_2 + ZnCy_2\ .\ 2\ KCy + K_2O_2Zn + 2\ H_2 + 4\ Au.$$

Christy also says:

According to the substitution reaction, one atom of zinc replaces two atoms of gold, or 1 ounce of zinc should precipitate 6.2 ounces of gold; whereas, as everyone knows, in practice 1 ounce of zinc will precipitate only one-fifth to one-fifteenth of an ounce of gold, or thirty to ninety times less than the amount called for by the reaction by substitution. According to the reactions I have suggested, in the absence of free cyanide of potassium and caustic potash 1 ounce of zinc should precipitate 3.1 ounces of gold; in the presence of a moderate excess of cyanide of potassium it should precipitate 2.06 ounces. The apparent discrepancy that seems still to remain between theory and practice is in reality due to the facts, first, that the free alkali (potash in particular) formed in the solution of the gold, or added to neutralize the free acid in the ore, also dissolves the zinc as potassium zincate; second, that an excess of potassium cyanide dissolves the zinc on its own account, both as the double cyanide and as the zincate of potassium; third, it should also be remembered that water containing dissolved oxygen attacks metallic zinc quite vigorously, forming hydrate of zinc.

According to Packard, the 60 pounds of zinc shavings required to fill the zinc boxes described above will precipitate the gold from about 1,500 pounds of 0.2 per cent solution per hour, the solution carrying from 0.1 to 0.8 ounce of gold per ton on entering the zinc box, and from 0.01 to 0.05 ounce on leaving it. The gold in wash waters and weaker solutions is less easily precipitated, a much longer contact with the zinc being required.

On cleaning up, the zinc shavings are washed and the finely powdered portions, called zinc-gold slimes, are screened through sieves varying in mesh, at the different mills, from one-fourth-inch mesh to 60-mesh, the coarse stuff being returned to the zinc box. In this country, where the zinc-gold slimes are treated at the mills, they are subjected to the action of an acid, such as sulphuric, which removes much of the zinc and other soluble bodies, and the residues are then washed, dried, fluxed, and melted. A few mills ship these slimes to smelters and refiners, but the difficulty of obtaining a satisfactory sample, and the almost constant wide disagreement between buyer and seller have led many smelters to refuse to handle them.

In discussing Professor Christy's paper Mr. Francis L. Bosqui stated[2] that at Bodie, Cal., after many discouraging failures, the following method of operating in treating the zinc-gold slimes was adopted, and has been followed with entire success:

The slimes and fine zinc are discharged directly from the zinc boxes into a redwood vat 6 feet in diameter and 2 feet deep. This vat is protected on the inside by several coats of paraffin paint, has a slight bottom incline for drainage, and is provided with a 2-inch discharge valve. Here the slimes are treated with sulphuric acid. After the destruction of the zinc, the zinc sulphate and the slight excess of acid present are diluted by filling the vat with warm water. Within an hour the bulk of the precipitate will have settled to the bottom. The supernatant liquor, to the amount of about 400 gallons, which still contains a small amount of gold slimes in suspension, is then siphoned off into a 10-ton settling vat.

The gold slimes are treated with a succession of these washes, the supernatant liquor being each time drawn off into the settling vat, until the amount of zinc sulphate remaining in the slimes is insignificant. The liquor siphoned off into the settling vat, which contains only a very small quantity of slimes in proportion to the total quantity obtained, is left to settle between clean-ups. The clear liquor is drawn off just before a succeeding clean-up, and at long intervals the precipitate is gathered from the bottom and melted.

The bulk of the slimes is finally discharged from the acid vat into a filter box. This box is provided, about a foot from the top, with a perforated partition which is closely covered with two thicknesses of ordinary mill blanketing. From the compartment beneath this filter the air is withdrawn by means of a steam ejector, and the water is thus removed from the slimes by suction. At the bottom of the box is a 1-inch discharge valve for drawing off the accumulated clear liquid. By occasionally scraping the filter blankets the passage of water through them is greatly facilitated. These blankets are removed and washed after each clean-up, and clean ones are substituted. The partially dried slimes from the blankets are then completely dried over a furnace and melted in crucibles. The zinc residues being thus pretty thoroughly removed from the slimes, the difficulties in melting are reduced to a minimum. * * *

For some time a considerable value went into the slag, which had to be shipped to the smelting works. But after a good deal of experimentation a very suitable flux has been found, which reduces the slag value to almost nothing. A dust chamber has been constructed in connection with the melting furnace, and an effective damper introduced in the course of the flue. The latter is closed at each charging of the crucible, and "dusting" is thus almost entirely avoided.

Our loss in melting has never been more than barely appreciable, and now, since the introduction of a dust chamber and damper, is wholly insignificant. The wonderfully close correspondence between our actual bullion yield and the extraction indicated by careful assays of charged and discharged tailings would in itself weaken the supposition of any considerable loss in melting. To be sure, our bullion is low grade, but we suffer no inconvenience from this except the small increase in cost of transportation and refining in proportion to the value of the bars.

Precipitants other than filiform zinc are sometimes employed to throw down the gold. Thus, at the Delamar mine, Nevada, the precipitation is by zinc dust,[1] with agitation: Molloy precipitates with sodium or potassium amalgam, Moldenhauer with aluminum, Johnston with pulverized carbon, Christy with cuprous chloride, and De Wilde with cupric sulphate. Precipitation is effected also by electricity, amalgamated copper plates being used in the Pelatan-Clerici process, and thin lead plates as cathodes, with iron anodes, in the Siemens-Halske process.

Electro-deposition processes seem to possess an advantage over zinc precipitation processes in that the presence of caustic soda makes no difference in the result, and that they are as effective with a weak as with a strong solution. Very weak cyanide solutions may therefore be used in the leaching vats. Charles Butters, who has been closely identified with the development of the cyanide process from its introduction into this country in practical form, and has had extensive professional experience in South Africa, says[2] that in our more modern plants the electrolytic and zinc processes are now used in combination for the recovery of the metal from cyanide solutions. The solution is first cleaned by the electrolytic process. It extracts from 90 to 94 per cent of all the products, including practically all of the copper. About 8 to 9 per cent of the electric box capacity is then filled with zinc, which, aided by the electric current, removes the small quantities of gold and silver remaining. By this combination the zinc is constantly at its best, as everything that would injure the surface of the zinc as a precipitating surface has been eliminated by the previous electrolytic treatment. At Butters' mines, in Salvador, an extraction of about 99 per cent of the values in solution is made on regular monthly runs. This process is used also at Virginia City, Nev., and at Minas Prietas, Mexico.

The following tables from Packard's paper clearly set forth some of the variations which obtain in the use of the cyanide process with precipitation by zinc in practice, with the results:

Mr. W. H. Davis has discovered that by subjecting foul cyanide solutions to the action of alternating electric currents the solutions are not only regenerated, owing to the precipitation of the foul matter present, but the resultant solution is more active and has a higher solvent power than a normal cyanide solution. He attributes this increased efficiency to cyanogen which has been set free in the electrolysis, being held dissolved in the solution. This process of treatment was introduced on a working scale at the Smuggler-Union mines, Colorado, in May, 1902, and it is claimed that by its use tailings carrying as low a value as $1.80 per ton have been treated at a profit, the average cost of treatment being 50 cents per ton. The published

statement[1] of the manager of these mines, comparing the results of the operations for the four months preceding with those for the four months succeeding the introduction of this process for regenerating the foul solutions, states that the application of the process resulted in a reduction of 29.73 per cent in the quantity of potassium cyanide consumed and an increase of 17.09 per cent in the quantity of gold and of 4.81 per cent in the quantity of silver extracted.

The results of simultaneous cyaniding, agitation, amalgamation, and electro-deposition are set forth in the following table, given by T. M. Chatard and Cabell Whitehead:[2]

[1] Contained arsenic and antimony.

[2] Contained silver chloride.

In this connection it may be noted that in Wagner's Chemical Technology[3] there is described a method of treating refractory ores, invented by W. Crookes, which consists in subjecting the powdered ore to the action of an alternating current in the presence of a solution of mercuric cyanide or of some other soluble salt of mercury.

The methods used in the Witwatersrand have been described recently by John Hays Hammond,[4] as follows:

The following description applies to the treatment of ores in the pyritic zones. Ores from the upper (oxidized) horizons of the reefs, which constitute but a small percentage of the ores treated, require a slight modification of the process.

The ground near the mines is level, and does not permit transportation by gravity; consequently the ore must be first elevated into the ore bins at the mill, and the tailings leaving the mill must be elevated for treatment by the cyanide process. This is done either by tailing pumps or, preferably, by tailing wheels. These are from 40 to 50 feet in diameter, and discharge the tailings into a launder, which, with a grade of about 3.5 per cent, carries them to the cyanide works. The auriferous pyrites are, to a large extent, taken out as concentrates by means of Spitzlutten (hydraulic classifier). About 10 per cent of the mill pulp recovered in this way consists of pyrites with coarse sand, a concentration of 10 to 1 being obtained. These concentrates are taken to tanks for separate treatment. From two to three weeks of treatment is required in order to obtain from this material a recovery of from 90 to 95 per cent of the gold it contains. A solution of about 0.25 to 0.3 per cent of cyanide of potassium is used. After passing over the Spitzlutten the tailings are run to Spitzkasten (pointed boxes), where the heavier sands are allowed to settle, while the lighter material (slimes) overflows, and is carried to the slime works for special treatment. The sands which settle in the Spitzkasten, representing about 70 per cent of the battery pulp, are continuously discharged by pipes leading from the bottom of the box, and are delivered by a hose or by an automatic revolving distributor to settling tanks, into which they are so fed as to be as thoroughly mixed as possible. This separation of the sands from the slimes has to be carefully made, so as to remove all clayey substances, the presence of which would otherwise prevent rapid percolation of the solution and the free access of atmospheric oxygen, which is essential to the solution of gold by cyanide.

Most of the modern plants have a system of double treatment, the tailings being settled in the settling tanks, when they are treated, after being allowed to drain, with a weak solution of cyanide of potassium. This addition of the cyanide of potassium is made rather for the purpose of saturating the sands with the solution than for thorough leaching, which would be difficult on account of the packing of the sands as they are settled, rendering percolation difficult. After the solution has been drained off, the sands from the settling tanks are discharged into the leaching

[3] Manual of Chemical Technology, R. von Wagner, translated by W. Crookes, 1892, page 191.

[4] Transactions of the American Institute of Mining Engineers, Vol. XXXI, pages 817 to 854: 1902.

tanks, placed immediately below the settling tanks, from which they are filled from discharge doors on the bottom of the latter. For a 200-stamp plant 16 steel settling and 16 steel leaching tanks are usually employed. From 3 to 4 settling and leaching tanks are used for the treatment of the Spitzlutten concentrates above described. The settling tanks are usually 40 feet in diameter and 9 feet high. The leaching tanks have the same diameter, but usually a foot less height. The capacity of these tanks is about 400 tons of pulp each.

In the leaching tanks the pulp is subjected to three treatments with cyanide of potassium. Where the MacArthur-Forrest process is used, the strong solution contains 0.25 per cent, the medium solution 0.2 per cent, and the weak solution 0.10 per cent of KCy. In the Siemens-Halske process the solutions are weaker, namely, the strong solution, 0.10; medium, 0.02; and weak, 0.01 per cent of KCy.

The treatment requires from four to seven days. From 130 to 150 tons of solution are usually employed for 100 tons of sand. After being allowed to drain, the sands are discharged through bottom discharge doors into trucks, in which they are removed to residues or tailings heaps. Here, again, elevation is necessary, on account of the flatness of the country, and is usually effected by the endless rope system. These tailings heaps are conspicuous throughout the mining district. By reason of the heavy winds prevailing at certain seasons of the year, they are becoming a great nuisance, and the question of their future disposition is one of the problems for the mining engineer.

The cyanide solution, after being drawn off from the leaching tanks, is taken to the precipitation boxes. The gold from the strong solution is precipitated in one set and that from the weak solution in another set of boxes. Precipitation is effected by either the MacArthur-Forrest or the Siemens-Halske process.

The MacArthur-Forrest process.—In this process the gold is precipitated by zinc, the solution passing upward through a succession of compartments, in which are placed zinc shavings or filings, resting on a movable tray of coarse screening. About twenty precipitation boxes, 20 feet by 3 feet by 3 feet 9 inches in size, are used. The gold bearing solution is brought into close contact with the zinc, causing the deposition of the gold, partly as a metallic coating on the zinc and partly as gold slimes, which sink to the bottom of the box. As the zinc is gradually dissolved by cyanide more is added.

Once or twice a month the boxes are emptied, and the gold slimes are treated with dilute sulphuric acid, then dried and melted in crucibles. The dried slimes contain about 15 to 20 per cent of gold, and after fluxing with borax and soda an ingot of 0.750 to 0.800 fineness in gold and 0.100 in silver is obtained. The slag, carrying from 5 to 50 ounces of gold per ton, is usually sold to smelters.

This precipitation process yields satisfactory results only with solutions containing more than 0.1 per cent of cyanide, the weaker solutions not being acted upon by zinc. An improvement of the method is the addition of lead to the zinc, whereby the combination of the two metals forms a galvanic couple, which also reacts with weaker solutions, such as are employed, for example, in the treatment of slimes.

The Siemens-Halske process.—In this process the solution flows through compartments very similar to the zinc boxes above described, but the zinc shavings are here replaced with lead strips (0.1 pound per square foot) or shavings hung between iron plates placed vertically and longitudinally in the box, about 4 inches apart. The lead strips are connected with the negative, and the iron plates with the positive, pole of a dynamo, and the solution is thus electrolytically decomposed, the gold being plated on the lead cathode. The iron plates are wrapped in canvas to prevent short circuiting. The current employed is from 2 to 3 volts, giving a current density of about 0.06 amperes per square foot of cathode. Once a month the lead sheets are removed and replaced, and the gold coated lead is melted and cupelled, yielding a bullion of 0.880 fine in gold and 0.100 in silver. The litharge is sold to smelters. The solutions passing through the treatment boxes are collected in tanks, and are made up to a proper strength by adding the necessary KCy.

The cost of the Siemens-Halske process is slightly greater than that of zinc precipitation, and the percentage of extraction is about the same. But the Siemens-Halske process may be applied to any solution, weak or strong.

A digest covering most of the patents issued by the United States Patent Office in certain of the subclasses of metallurgy, and subclass 15 of electrolysis, up to 1904, is given in the Appendix.

Scope.—From the description of its mode of operation it is evident that the "straight cyanide process" is readily applicable to free milling ores which are free from mineral substances that would foul the solution or consume the cyanogen salt, and the gold in which is finely divided and so exposed that the cyanide solution may come in intimate contact with it. In old tailings which have been exposed for years to the action of the weather, whereby the sulphurets have been oxidized and the acids and salts formed, dissolved and washed away, there has been found much material ready at hand for immediate treatment in the simplest manner. The problem is comparatively simple, also, in the case of siliceous gold bearing deposits free from sulphurets, but the ore must be crushed, and in many instances it is more economical to concentrate it than to expose the entire mass to the action of the cyanide solution. Moreover, even in the case of neutral and otherwise suitable ores, the fine particles of metallic gold may be so enveloped in an impermeable covering—such as iron or aluminum hydroxide—as to necessitate a preliminary treatment, such as roasting, to rupture the envelope. An example of this kind is found in the ores of the Republic gold mine, Washington, described by T. M. Chatard and Cabell Whitehead.[1] When coarse gold is mingled with the fine, it is usually more economical to separate the coarse gold by amalgamation than to await the slow-acting process of solution. With tailings in which the sulphurets are but partly decomposed and which still contain ferrous and ferric salts and sulphuric acid, cyaniding may be preceded by washing and neutralization.

The treatment of refractory ores is determined, in each case, by the chemical and physical characteristics of the ore under consideration. Hence, we find that cyaniding may be combined not only with crushing, roasting, concentration, and amalgamation, but also with smelting and chlorination. In some instances it is most advantageous to separate the ore into fractions, each of which is subjected to a different treatment. In fact, it is essential to success that the ore should be thoroughly examined by a competent metallurgical chemist before any investment in a plant for treatment

[1] Transactions of the American Institute of Mining Engineers, Vol. XXX, pages 419 to 423.

by chemical processes is made, and also that the cyaniding process should be under chemical supervision, in order that, by assays of the ore and tailings and by analyses of the ore and the cyanide solutions as they enter and issue from the zinc boxes, and of the solvent during preparation and regeneration, a complete check may be made upon the operation in each of its stages.

Working costs.—It is obvious that the cost of the cyanide process will vary at the different plants, according to the variations in the chemical composition and physical structure of the ore treated, in the condition of the ore at the time of treatment—that is, whether it be in the form of sand or slimes—in the character of the process and the apparatus used; in the location of the mill with regard to the supply of ore or tailings used; and the source of power, water, materials, and labor. According to H. M. Chance,[1] in the Black Hills, S. Dak., the cost of smelting siliceous ores was between $4.75 and $5.75 per ton; the cost of chlorination, from $3.50 to $4.50 per ton; and the cost of the cyanide treatment, possibly from $3 to $3.75 per ton. From the Report of the Director of the Mint, for the calendar year 1901,[2] it appears that in that year there were 11 cyanide plants in active operation in South Dakota, having a united capacity of over 1,500 tons daily, and that some of these mills claim to be able to treat ore at a cost not exceeding 80 cents per ton, though the average cost is probably nearer $1.50 per ton. Julian and Smart[3] give 21 different detailed accounts of costs at mines in Australia, Africa, and the United States, the results ranging from 2s. 1.23d. per ton by the Siemens process, in South Africa, to 17s. 1.02d. per ton by the Diehl process, in Western Australia.

Effect on the world's supply of the precious metals.—The data collected at this census deal only with the output of the United States for 1902. There are no collected data to afford a comparison of the condition of this industry in that year with the condition during any previous period since its introduction into this country, in 1891. But the consensus of evidence, as presented in current literature, indicates that the industry has been constantly growing, that new plants are going up each year, and that established ones are increasing their capacity. This is true not only of the United States, but also of Africa, Australia, New Zealand, Mexico, and the other gold producing countries; from each are coming increased supplies of the precious metals extracted from low-grade ores and tailings.

CALENDAR OF EVENTS AND DISCOVERIES RELATIVE TO THE PRECIOUS METALS.

1530–1540. Pillage of Peru.
1547–1548. Discovery of Guanajuato silver mines in Mexico.
1577. Discovery of gold in Brazil.
1670. Discovery of placers of Garazua.
1680. Discovery of placers of Minas-Geraes.
1704–1728. Silver mines opened in Russia.
1743. Discovery of gold in the Ural.
1848. Discovery of placers in California.
1848. Introduction of Plattner's chlorination process at Reichenstein in Silesia.
1851. Discovery of placers in Australia.
1853. Introduction of hydraulic mining in California.
1853. Maximum annual production of gold in California, amounting to $65,000,000 for the year.
1858. Introduction of chlorination process at Grass Valley, California.
1866. Invention of dynamite.
1886. Opening of the "banket" reef of the Rand, South Africa.
1889. Development of Manké's method of bessemerizing copper mattes, and the successful refining of this impure copper by electricity.
1890. Introduction of the cyanide process in the Rand, South Africa.
1897. Discovery of placers in the Yukon.

Apart from the phenomenal annual increase in the production of gold during the period from 1841 to 1855, which includes the discoveries of the rich placers of California and Australia, the increase in the world's production during the last decade of the nineteenth century was unprecedented. It was most marked during the period from 1891 to 1895, following the opening of the "banket" reef of the Rand and the introduction of the cyanide processes, but it was continuous throughout the decade, except during the period of the Boer War, and the output of gold in 1902 exceeded that of any other year of our record except 1899. It is true that the use of the cyanide process is only one of several causes contributing to this result, but that it is an important one is indicated by the fact that the returns for this census show that the amount of gold recovered by the use of the cyanide process in the United States in 1902 exceeded that won throughout the whole world by all existing means during any year of our record up to 1661, and probably up to 1701.

APPENDIX.

DIGEST OF UNITED STATES PATENTS RELATING TO CYANIDE PROCESSES FOR THE RECOVERY OF PRECIOUS METALS.

This digest covers most of the patents included in the following classes and subclasses of the United States Patent Office classification:

Class 75.—Metallurgy.
Subclass 18.—Solutions and Precipitation.
Subclass 86.—Solutions and Precipitation—Apparatus.
Subclass 185.—Cyanides.
Class 204.—Electrolysis.
Subclass 15.—Aqueous Bath, Ores.

Some of the patents in these categories are quite foreign to the subject under consideration, and many but indirectly related to it. It has been thought, however, from the form which discussions of patent issues often take, to include the latter. The aim in making the digest has been to give such a sketch as will indicate the nature of the invention and what is claimed by the inventor, this generally being done by an actual abstract from or paraphrase of the words of the letters patent, but no responsibility is assumed for the opinions, theories, or claims thus set forth. Other related patents may have been granted which do not appear in this digest, because they are not embraced in the subclasses enumerated. Thus, the patents number 229586, to Thomas C. Clark; 236424, to H. W. Faucett; and 244080, to John F. Sanders, do not appear in this digest, because the first two are classified under subclass "Reducing and Separating—Disintegrating Ores," and the third under subclass "Reducing and Separating—Gold and Silver," and neither of these subclasses is included in this digest.

CLASS 75.—METALLURGY.

Subclass 18.—Solutions and Precipitation.

15542—August 12, 1856. W. Ziervogel. *Improvement in processes of separating silver from the ore.*

The application of water or a solution of sulphate of copper slightly impregnated with sulphuric acid instead of lead, quicksilver, or salt, hitherto used for this purpose, to the process of separating silver from copper and other ores, rendering thereby this separation easier, shorter, less expensive, and not noxious to the health of the operator.

19991—April 20, 1858. I. Gattman. *Improvement in the treatment of sulphureted ores.*

The use of sulphuric acid in connection with the hydrate, carbonate, or sulphate of potash or soda, or with any compound thereof, in the mode of working the native metallic sulphurets.

35842—July 8, 1862. J. Shaw. *Improved apparatus for saving silver from waste solutions.*

Attaching to the waste pipe of the sink or basin into which persons using silver in solutions suffer them to be wasted, a vessel so arranged and constructed that the liquids passing from the sink shall run into, through, and out of said vessel, and between the time of entering said vessel and escaping therefrom shall be brought into contact with such chemicals or metals as will cause the whole or any part of the silver contained in solution to be precipitated and retained in said vessel, while the worthless material is allowed to escape. (This patent was reissued as follows: Reissue 1651, April 5, 1864; reissue 3506, June 15, 1869; reissue 4030, June 14, 1870; reissue 4969, Division A, July 9, 1872; and reissue 4970, Division B, July 9, 1872.)

46875—March 21, 1865. W. Brückner. *Improved process for refining amalgam.*

The application and use of bichloride of copper, or its equivalent, together with iron pyrites and salt, without reference to the exact proportions of each ingredient.

46983—March 28, 1865. G. W. Baker. *Improvement in treating ores.*

In order to produce a valuable metal or metals now almost wholly cast away in the treatment of auriferous and argentiferous pyrites, the inventor proposes to take the calcined ores as they come from the furnaces, and, having them well pulverized, subject them to the action of sulphurous acid in tanks located over the main discharge flues of his furnaces, whereby a sufficient heat may be obtained to assist in the reaction of the acid before mentioned. The sulphurous acid thus used is to be formed and collected by compelling the sulphurous vapors discharged from the roasting furnace to pass over, through, and in contact with water, so that sulphurous acid will be formed and collected in a properly arranged tank or tanks, from whence it may be conveyed to the ore tanks, and there mixed with the ore thoroughly by agitation in any manner most convenient. After the ore has been subjected to the action of the acid for a couple of hours the oxide of copper will be replaced by a sulphate soluble in water, and the oxide of iron will be partially brought into the same condition. Should there be any gold or silver held in solution these metals will be reduced to the metallic state. The solution is then drawn off by siphon or otherwise and conveyed to another tank or vat for subsequent treatment, either by cementation or precipitation for the copper and evaporation for the sulphate of iron. The ore thus treated may then be lixiviated by water to wash out all the acid, and this water, which will still hold some dilute solution of the baser metals, may be conveyed to the acid tank and used for the further formation of sulphurous acid. By this means the most concentrated solution is alone permitted to pass to the tank or vat for further treatment. It may be considered a well-settled fact that in all processes of calcination some portion of the precious metals, if such ores are under treatment, escape mechanically or in a vaporized form. This loss, great or small, as the case may be, has heretofore been to a great degree irreclaimable. It is claimed as a part of this improvement that such loss, whether mechanical or in the form of vapor, is wholly prevented by arresting their escape and returning them, either in solution or in the sediment of the liquid acid, to the ore when treated in the ore tanks.

47286—April 18, 1865. W. L. Faber. *Improved process of working silver ores.*

The invention consists in a process which is divided in eight different manipulations, viz, smelting the ore, pulverizing, roasting at low heat, extracting sulphates with water, roasting residue with salt, melting with soda, precipitating silver, precipitating copper.

49637—August 29, 1865. S. F. Mackie. *Improved process for treating ores.*

The mode of obtaining a rich gold residue from ores of gold by treating the ores by roasting and fusing, and subjecting the roast to the action of acids.

52834—February 27, 1866. J. H. Elward and J. L. Hayes. *Improved process for separating gold and silver from ores.*

The process of oxidizing sulphurets containing the precious metals and converting them into sulphates by the use of solutions of nitrates.

56765—July 31, 1866. E. Lamm. *Improved method of preparing gold for dentists.*

The use of saccharine substances to precipitate gold from its solutions, thereby forming a mass of crystal shreds extremely useful and convenient for dental and other purposes.

148356—March 10, 1874. J. Douglas, Jr. *Improvement in extracting silver from its ores.*

The process of utilizing the waste liquors of the ordinary ore-chloridizing process, by allowing the insoluble matters contained in said liquors to precipitate, and then evaporating the clear supernatant liquid to obtain the soluble chlorides, which are reapplied in treating fresh ore.

207695—September 3, 1878. J. Tunbridge. *Improvement in separating metals from waste solutions.*

The process of separating precious metals from watery solutions, in which said metals are suspended by passing the watery solutions or suds through a bath of oil or hydrocarbon liquid.

219961—September 23, 1879. F. M. Lyte. *Improvement in extracting metals from ores.*

In the treatment of ores containing lead, zinc, silver, and copper, the method of securing the neutralization of the solutions of soluble bases, economizing acid, and carrying over the least possible quantity of silver and lead, which consists in treating the raw ores with an acid solution partially saturated by previous attack on the ores, and treating the partially exhausted ore by raw acid before the latter is admitted to the raw ore, the said steps being conducted in a continuous, alternate, and methodical manner.

227963—May 25, 1880. W. M. Davis. *Depositing gold from its solutions.*

The process of obtaining gold from its solution by bringing said solution in contact with carbon, and thereby depositing the gold upon it, and of subsequently obtaining the gold from the carbon by calcination or other equivalent means.

287737—October 30, 1883. C. A. Stetefeldt. *Process of treating sulphides.*

The process of treating sulphides, such as those obtained from the lixiviation process of silver ores, said process consisting in first exposing said sulphides to the action of dilute sulphuric acid in the presence of nitrate of soda, then converting the nitric oxide which escapes into nitrous acid and nitric acid, and finally carrying on the process by means of a mixture of nitrous acid and nitric acid with dilute sulphuric acid.

288838—November 20, 1883. J. Miller. *Process of recovering metallic particles from water.*

The method of recovering metals in suspension in liquid, consisting, essentially, in forcing such liquid through a filtering medium having a capacity of expansion, and resisted by a rigid inclosing vessel or medium, and then burning the filling material or otherwise separating the metal therefrom.

290258—December 18, 1883. J. Miller. *Apparatus for collecting and saving metallic particles.*

An apparatus for recovering metals or metallic compounds in liquids, consisting of a rigid tank, perforated on one side, in combination with an entrance pipe, provided with a trap and a pressure device.

290458—December 18, 1883. J. Miller. *Method of recovering metals.*

The improved method for recovering metallic particles, slimes, and similar material containing metal from liquids, consisting, essentially, in conducting the liquid and metal bearing material to a settling tank, allowing the gangue to fall to the bottom, drawing off the liquid, and forcing it under hydrostatic pressure through a filter press, and removing and drying the filtrate.

292605—January 29, 1884. C. P. Williams. *Art of extracting gold by means of alkaline sulphides.*

In the art of extracting gold from ores and artificial gold bearing products by means of alkaline sulphides, the process, which consists in mixing the gold bearing material with carbon and an alkaline sulphate (or the equivalents of such carbon and alkaline sulphate), calcining said mixture in a nonoxidizing atmosphere at a temperature below the point of fusion of the charge, cooling the mass out of contact with the air, and leaching the cooled mass with water to dissolve out the soluble sulphides, and recovering the gold therefrom by precipitation.

377809—February 14, 1888. T. Kiddie. *Process of separating precious metals and impurities from solutions of copper, salts, ores, mattes, etc., in acids.*

The process of removing precious metals and impurities from copper mattes, ores, bullion, etc., consisting in dissolving the same after desulphurization and calcination in sulphuric acid, in quantities sufficient to form a neutral solution, and in adding iron hydrates to the neutral solution, whereby the impurities are precipitated and settle with the precious metals not dissolved by the sulphuric acid, leaving a comparatively pure solution of iron and copper salts.

381809—April 24, 1888. R. Oxland and C. Oxland. *Treatment of ores and materials containing sulphur for the extraction of metals and other constituents.*

The method of treating raw or unburned sulphuret ores of copper and iron to render the copper soluble in water, while leaving the iron for the most part insoluble and rendering the sulphur in the ore available for the manufacture of sulphuric acid, consisting in mixing the finely pulverized ore to a semifluid consistency with sulphuric acid and solution of persulphate of iron, heating the mixture to a temperature such as to evolve sulphurous-acid vapor, and collecting and condensing such acid vapor.

387688—August 14, 1888. A. H. Low. *Extraction of zinc from ores.*

The process of extracting zinc from ores containing precious metals, consisting in leaching the ore with an aqueous solution of sulphurous-acid gas to dissolve out the zinc, and then boiling the leached liquor to expel the sulphurous-acid gas and cause a precipitation of the zinc.

403615—May 21, 1889. E. H. Russell. *Process of leaching ores with hyposulphite solutions.*

The process of extracting metal from ores and metallurgical products, which consists in introducing into the ore or product carbonate of soda, then treating the mass with a solution of sulphate of copper, and then treating it with a hyposulphite solution.

413808—October 29, 1889. J. S. MacArthur. *Process of leaching ores.*

The process of treating ores containing oxides or carbonates of earth metals, consisting in first subjecting such ores to the action of a proportionate quantity of a solution of a ferrous salt or a bisul-

phate of an alkali to combine with the oxides or carbonates of earth metals, and then treating the ores with an acid or salt to obtain the contained metals.

421031—February 11, 1890. R. Pearce. *Process of extracting silver from copper ores, mattes, and other copper products.*

The process of separating silver from ores or mattes containing base metals, which consists in mixing with the finely pulverized ore or mattes a quantity of sulphate of sodium or potassium equal to 2 per cent, then roasting the mixture, and finally leaching out by hot water to obtain the sulphate of silver.

440143—November 11, 1890. E. Dode. *Process of separating gold and platinum from other metals in solution.*

The process of separating from an acid solution of gold, platinum, copper, and tin the metallic constituents of said solution, which process consists in first subjecting the entire solution in the presence of ether to agitation until the ether becomes yellow, in then decanting the remaining solution from the yellow ether, in then subjecting said remaining solution to agitation in the presence of essence of lavender until the essential oil becomes brown, and in then decanting from the brown essential oil the remaining solution and adding thereto ammonia.

442016—December 2, 1890. C. L. Coffin. *Process of treating ore containing lead, silver, and zinc.*

The process of treating ore containing lead, silver, and zinc to remove the zinc preparatory to smelting, consisting in first roasting the ore, then leaching the ore, filtering the leach fluid through carbon, then subjecting the leach fluid successively to the action of metallic lead and of metallic zinc, and finally precipitating the zinc held in solution in the leaching fluid.

444997—January 20, 1891. W. West. *Process of treating zinc ores.*

The process of eliminating zinc from complex ores, which consists in roasting the ore to form sulphurous-acid gas and oxidize the zinc, then cooling this gas to a temperature of 180° F. or below, and passing the same in gaseous form in conjunction with steam and without oxidation into sulphuric acid through a previously roasted charge to form soluble sulphite of zinc, and then immediately leaching out and separating the zinc sulphite with water at a temperature below 180° F.

449814—April 7, 1891. S. W. Cragg. *Lixiviation process of and apparatus for the extraction of gold or silver.*

The process of restoring the oxygen in a hyposulphite solution in the lixiviation process, which consists in passing a current of air through the ore pulp while the said solution is in contact therewith, and a leaching vat, a grating at the top thereof through which ore pulp and water are introduced to the interior of the vat, and a system of crossed separated bars within the vat through which the ore pulp and water pass, combined with an endless-apron filter on which the ore pulp and water fall from the said crossed bars, a trough beneath the filter to receive the water, and a lixiviation vat into which the apron filter discharges the ore pulp.

471616—March 29, 1892. J. Leede. *Process of treating refractory ores.*

The continuous process of treating refractory auriferous and argentiferous ores, which consists in subjecting the ore to the continuous action of an oxidizing blowpipe flame in direct contact with the ore at a moderate heat, intermittently subjecting the heated ore to the action of water, agitating the ore, and then repeating the operation at a higher heat, and finally subjecting it to an oxidizing roast without chills, whereby the volatile elements are driven off, the oxidizable elements or compounds are oxidized, and the precious metals are left free and in suitable condition for amalgamation or chlorination.

473186—April 19, 1892. P. C. Choate. *Method of producing metallic zinc.*

The process of producing metallic zinc from its ores, which consists in separating the zinc and the equally volatile and more volatile constituents from the less volatile constituents of the ore by the use of heat and a reducing agent, then volatilizing and oxidizing the reduced metal, thereby obtaining a condensed oxidized fume, subjecting this fume to a moderate heat in order to expel its soluble constituents more volatile than zinc, treating the remaining product with dilute sulphuric acid as a solvent, and finally subjecting the resulting solution to the action of an electric current to precipitate the zinc.

481499—August 23, 1892. G. T. Lewis and C. V. Petraeus. *Process of treating sulphide ores of zinc and lead.*

The process of recovering lead and zinc from sulphureted lead and zinc-lead ore, which consists in roasting the ore, then smelting the roasted mass and exposing the fumes or volatile matter produced by said smelting to the action of the gases which are volatilized in the roasting of said ore, together with water, and then separating the zinc solution from the insoluble lead compound and recovering the zinc and lead.

483924—October 4, 1892. T. S. Hunt and J. Douglas. *Process of separating copper from cupriferous nickel ores.*

The method of separating the copper from a solution containing copper oxide and oxides of iron and nickel to produce nickeliferous iron, which consists in first adding common salt to the said solution, then passing a stream of sulphurous acid gas through the said solution, then precipitating the last traces of the copper in the form of metallic copper, and subsequently crystallizing out the nickel and iron and calcining and smelting the product to obtain nickeliferous iron.

483972—October 4, 1892. C. Whitehead. *Process of treating mixtures containing sulphides of precious metals and copper.*

The process of treating a mixture containing sulphides of the precious metals and of copper, which consists in mixing the sulphides with solution of a salt of silver, whereby a soluble salt of copper is formed and sulphide of silver is precipitated, separating the solution containing the copper from the residue containing the precious metals, roasting this residue to reduce the precious metals to the metallic state, treating the reduced metals with hot sulphuric acid to dissolve the silver, separating the silver solution from the residue, and melting the final residue.

490068—January 17, 1893. F. P. Dewey. *Process of treating mixtures containing sulphides.*

The process of treating mixtures containing sulphides of silver and copper, which consists in heating the sulphides with strong sulphuric acid to convert the sulphides into sulphates and dissolve the sulphate of silver, adding water, to bring the sulphate of copper also into solution, drawing off the resultant solution, precipitating the silver therefrom by metallic copper, and recovering the sulphate of copper from the remaining solution.

490193—January 17, 1893. A. French. *Process of obtaining gold, silver, and copper from ores.*

In processes for obtaining gold, silver, and copper from ores, the treatment of the ores by pulverizing, mixing therewith small percentages of niter cake or bisulphate of soda and common salt, furnacing at a red heat, and then leaching.

497473—May 16, 1893. W. R. Ingalls and F. Wyatt. *Process of treating complex or sulphide ores.*

The process of treating complex sulphide ores, which consists, first, in subjecting the ore to a sulphatizing roasting; second, lixiviating the roasted ore with water and sulphuric acid and re-

moving the iron therefrom if necessary; third, precipitating the zinc from said solution in the form of carbonate or carbonate and hydroxide by the use of sodium carbonate and subsequently converting the same into zinc oxide; fourth, evaporating the sodium sulphate obtained from the zinc sulphate solution and heating the same with sodium chloride and coal to convert it into sodium sulphide; fifth, converting the sodium sulphide into bicarbonate of soda by dissolving the same in water and treating the solution with carbonic acid gas; and lastly, converting the bicarbonate of soda into sodium carbonate by heating the same to drive off the hydrogen and carbonic acid gas.

509058—November 21, 1893. E. Waller and C. A. Sniffin. *Method of concentrating ores.*

The method of concentrating argentiferous lead carbonate ores, which consists in dissolving out lead from the ore with the aid of acetic acid, real or combined, and water, out of contact with the air whereby the lead and carbonic acid eliminated from the ore are rendered capable of utilization in the arts, and the undissolved silver is concentrated in the residue.

509633—November 28, 1893. D. K. Tuttle and C. Whitehead. *Process of treating precious metal bearing slimes.*

The process of treating precious metal bearing slimes, which consists in subjecting the slimes to the action of dilute acids to dissolve the metals and oxides soluble therein and to the action of a solution of a salt of silver to remove metals more electro-positive than silver that are present in the metallic state.

509634—November 28, 1893. D. K. Tuttle and C. Whitehead. *Process of refining slimes from the electrolytic refining of copper.*

The process of treating slimes from the electrolytic process of refining copper, which consists in removing arsenic, antimony, tellurium, bismuth, and other impurities present as oxides by treating the slimes with dilute acid and heating the purified slimes with strong hydric sulphate.

513490—January 30, 1894. S. H. Emmens. *Process of treating zinc-lead-sulphide ores.*

The process of treating zinc-lead-sulphide ores carrying gold or silver or gold and silver, which said process consists in, first, finely comminuting the ore; secondly, roasting the same in an oxidizing atmosphere; thirdly, leaching such roasted ore with water containing ferrous sulphate; fourthly, leaching such once leached ore with an aqueous solution of ferrous and ferric sulphates; fifthly, leaching such twice leached ore with water containing ferrous sulphate; and sixthly, removing iron from the zinc sulphate solution obtained by the first and second of the said leachings by mixing such solutions together and heating them.

516016—March 6, 1894. W. R. Ingalls and F. Wyatt. *Treatment of ores of zinc.*

The process of treating ores of zinc, which consists, first, in subjecting the ore to an oxidizing roasting; second, lixiviating the roasted ore with water and sulphuric acid; third, separating one-fourth of the zinc-sulphate solution thereby formed from the rest and precipitating the zinc from said separated portion by means of a sulphide of an alkaline base; fourth, evaporating the remainder of the zinc-sulphate solution to dryness and mixing the precipitated sulphide therewith; and lastly, heating the mixture in a suitable furnace whereby sulphurous anhydride gas is evolved.

518890—April 24, 1894. L. Klöz. *Process of extracting zinc from ores.*

The process of treating zinc ores, which consists, first, in the preparation of a concentrated solution of sulphurous acid; second, in leaching the ores or furnace products with this solution to form a concentrated zinc sulphite solution free from sulphates; and third, scattering this solution by steam to dispel the sulphurous acid and precipitate the zinc sulphite.

527473—October 16, 1894. P. Argall. *Cyanide and chlorination process for treating gold or silver bearing ores.*

In the process of preparing gold and silver bearing ores for the extraction of the precious metals, the improvement consisting in separating the slime from the granulated ore, preventing the forming of acid in the slime by mixing lime therewith, and then forming the mixture into lumps for burning.

541374—June 18, 1895. E. B. Mierisch. *Process of extracting gold and silver from their ores.*

The process of extracting gold and silver from oxidated or roasted ores, which consists in mixing the ground ores with sodium hydrate, mixed with a corresponding quantity of calcium hydrate, then subjecting the mixture to the action of chlorine, whereby the ores are acted upon by chlorates, and hydrochlorites formed "in statu nascendi," and then leaching the lye with a concentrated sodium-chloride solution, the deterioration of which is prevented by the addition of the calcium hydrate to the sodium hydrate.

541447—June 18, 1895. H. F. Watts and A. Coan. *Process of reducing zinc slimes.*

The process of treating zinc slimes containing the precious metals, which consists in first treating the same with dilute sulphuric acid for the purpose of removing metallic zinc, washing the residue to remove the soluble salts and the remaining acid, and boiling the residue thus formed with concentrated sulphuric acid to dissolve the cyanide of zinc and the other salts thereof which are insoluble in the dilute acid.

541659—June 25, 1895. J. J. Crooke. *Process of and apparatus for extracting silver from its ores.*

The process of extracting silver from its ores, which consists in roasting the ores with chloride of sodium, treating the roasted mass with a hot aqueous solution containing chloride of sodium, nitrate of copper, and sulphuric acid, and recovering the silver from the solution.

544490—August 13, 1895. H. Brewer. *Process of utilizing waste lye.*

The process of treating zinciferous or cupriferous lyes resulting from the lixiviation of chlorinated roasted ores, which consists in chemically extracting the metals in the lye, except the zinc, removing the sodium chloride by concentration of the lye, extracting the zinc and chlorine from the remaining lye electrolytically, and effecting the chemical extraction in such manner that the final lye will consist essentially of a solution of calcium chloride.

544612—August 13, 1895. A. Crossley. *Process of manufacturing zinc.*

The process for the manufacture of zinc oxide, which consists in adding sulphuric acid to the metallic ores or compounds, heating the mixture and converting the lead present to an insoluble salt, and depositing any silver or gold present, then diluting with water and converting the other metals present to soluble salts, filtering off the clear liquor, then treating the clear acid liquor filtered off with an alkaline sulphide, precipitating the copper as copper sulphide, then filtering the liquor from the precipitate, treating with an alkali until neutral, passing chlorine into it until all manganese and iron present form manganic and ferric oxides, which are thrown down by a slight excess of alkali, adding an excess of alkali to bring the zinc oxide into solution, and then precipitating the zinc oxide, and filtering off the liquor therefrom.

547587—October 8, 1895. C. V. Petraeus. *Method of extracting zinc from complex ores.*

The method of separating zinc from complex ores where it is found as a sulphate or sulphite, which consists in crushing the ore, roasting it, dissolving out the soluble zinc salts in water, adding a solution of sulphuric acid to dissolve out any zinc oxide, introducing live steam to the mixture of ore and solvents to thoroughly mix and heat them, separating the solution of sulphate of zinc from the

insoluble parts of the ore, adding chloride of calcium to the solution to convert the zinc into a chloride, separating the solution of zinc chloride from the precipitated calcium sulphate and finally adding quicklime to the solution of zinc chloride to precipitate the zinc as zinc oxide.

556690—March 17, 1896. G. O. Pearce. *Process of extracting gold from solutions.*

The process of recovering gold and platinum metals from aqueous solutions of these metals, which consists in passing said solutions through a mass of vegetable carbon having associated with it sulphate of iron, oxalic acid, and tartaric acid.

559614—May 5, 1896. G. A. Schroter. *Extraction of precious metals.*

The process of extracting precious metals, particularly silver, from ores and metallurgical products, which consists in leaching the crushed and chloridized ore with a concentrated solution of brine to which has been added a small per cent (one-half to 4 per cent approximately) of a soluble salt of copper.

561544—June 2, 1896. F. P. Dewey. *Process of treating sulphides.*

The process of treating mixtures containing sulphides of silver and copper, which consists in heating the mixture with strong sulphuric acid, adding water, adding more mixed sulphides, separating the solution of sulphate of copper from the residue containing the sulphide of silver, and heating the sulphide of silver with strong sulphuric acid to convert it into sulphate.

561571—June 9, 1896. F. P. Dewey. *Process of treating mixtures containing sulphides.*

The process of treating mixtures containing sulphides of silver and copper, which consists in heating them to a temperature at which the sulphur is oxidized, in an excess of sulphuric acid sufficient to convert the sulphides of silver and copper into sulphates, and bring the sulphate of silver into solution outside of the mass of material treated, thereby oxidizing the sulphur, converting the sulphides into sulphates, and bringing the sulphate of silver into solution in the acid outside of the mass of material acted upon.

571369—November 17, 1896. B. Hunt. *Process of refining gold and silver bullion.*

The process of refining bullion slimes by first roasting the slimes to decompose all cyanogen compounds and carbonaceous matters and then treating the roasted slimes with nitric acid.

586159—July 13, 1897. H. Brewer. *Process of treating zinc sulphide ores.*

In a process of treating zinciferous sulphate lyes resulting from the lixiviation of chlorinated roasted zinc sulphide ores, adding sodium chloride to such lye to saturation or in excess, and crystallizing out the resulting sodium sulphate (Glauber salt) by refrigeration as a by-product.

587128—July 27, 1897. E. F. Turner. *Process of treating argentiferous sulphide ores.*

In a process for the extraction of the metal of compound sulphide ores, disintegrating and decomposing the latter by the combined action of aqueous and gaseous hydrochloric acid, neutralizing the acid gases evolved whereby sulphureted hydrogen is obtained, heating the disintegrated ore by means of such sulphureted hydrogen, collecting the sulphur dioxide resulting from the combustion, bringing this gas into contact with sodium chloride in presence of heat, whereby hydrochloric acid gas and sodium sulphate are obtained, and utilizing the former in the process of disintegration.

588476—August 17, 1897. H. A. Rhodes. *Process of separating gold and silver or other precious metals from their ores.*

In chemical processes for the separation of gold or other precious metals from their ores, slimes, or compounds, the method of preparing the ores by adding thereto a self hardening, binding material and forming a porous and rigid mass of the compound whereby the precious metals contained therein are freely acted upon by the solvent.

589959—September 14, 1897. J. J. Crooke. *Process of treating copper sulphides.*

The process of recovering silver or gold and extracting copper in a metallic condition from copper sulphides associated with iron sulphides, which consists in roasting the pulverized sulphides with sodium chloride at a low heat, leaching the roasted mass with a solution whereby the iron sulphides are largely converted into oxides and the silver and gold are dissolved by and removed with the solution, recovering the silver and gold from the solution, roasting the residuum or tailings, fluxing the roasted tailings with silica and pulverized carbon, gradually melting the roasted and fluxed charge to convert the oxide of iron into metallic iron and desulphurize the copper sulphides to liberate metallic copper and form an iron silicate slag, removing the slag from the melted copper, adding a small per centum of silica to convert any remaining iron oxide or metallic iron into an iron silicate slag, and removing this slag from the copper.

602295—April 12, 1898. E. A. Ashcroft. *Treating solutions or ores containing zinc for recovering zinc as oxides.*

The process of treating neutral zinc solutions for the production of zinc oxide, which consists in first converting the neutral zinc salt into basic zinc salt by the addition of zinc oxide and then intimately mixing with said basic zinc salt, carbon in approximately the proportion of one-twentieth of the weight of the zinc to be recovered, and heating the mixture to a temperature approximating the melting point of aluminum.

623154—April 18, 1899. H. Howard. *Extraction of zinc and copper from ores.*

The process of extracting zinc and copper from ore or residue, which consists in treating the same with aqua ammonia and ammonium sulphate; separating the copper from the resulting solution; adding sufficient soda to combine with all of the sulphuric oxide present and form sulphate of soda, and evaporating the solution to drive off ammonia, the latter being collected in water; and treating the residue with water to dissolve out the sulphate of soda, the zinc oxide remaining.

624000—May 2, 1899. J. Durie. *Method of reducing metallic sulphides.*

In the process of causing the solution of metallic sulphides containing lead, subjecting the sulphide ore to a solution of sulphuric acid and a nitrate of an alkali metal at a temperature of about 212° Fahrenheit, washing and filtering the lead sulphate obtained therefrom, dissolving the said sulphate, precipitating by carbon dioxide, washing and drying the precipitated hydrated carbonate of lead, and recovering the sulphur.

625433—May 23, 1899. M. Body. *Process of treating sulphureted ores.*

In the process of treating sulphureted ores of a complex nature, comminuting and melting the ore in presence of an alkaline salt and carbon, whereby alkaline polysulphides soluble in water are formed, plunging the melted mass into water, whereby a magnetic precipitate is formed and the polysulphides dissolved in the water, separating the solution from the precipitate, subjecting the same to the action of air and sulphurous-acid gas forced thereinto, whereby monosulphides of iron, together with the precious metals, are precipitated, maintaining the alkalinity of the solution during the operation of precipitation by addition of an alkaline substance, as lime, separating the solution from the monosulphide-of-iron precipitate, extracting from the latter the copper and then the precious metal, and separating the arsenic and antimony from the solution by precipitation.

627024—June 13, 1899. R. Threlfall. *Method of treating flue dust and fume obtained from sulphide ores.*

In the treatment of flue dust and fume from sulphide ores, the separation of the zinc from the lead constituents by leaching out the former by means of a solution of alkali metal hydrogen sulphate.

630951—August 15, 1899. L. Vanino. *Wet process of extracting silver from its haloid salts.*

The wet process of extracting silver from its insoluble haloid salts, which consists in mixing said haloid salts with a watering solution of alkaline agents, and adding formic aldehyde in the cold.

635056—October 17, 1899. D. O'Keefe. *Process of treating ore.*

The process of treating ore, consisting of roasting the same while being agitated, for the purpose of mechanical disintegration, subjecting the ore to hydrogen gas under pressure, afterwards to chlorine gas, and then leaching the same with hot salt water.

635695—October 24, 1899. C. Martin. *Process of chemically preparing and treating rebellious ores.*

The process of effecting the separation of gold, silver, tin, lead, and platinum, in pulverized rebellious ore containing arsenic and antimony, which consists in effecting sulphurization and disintegration of the said ore, producing a sulphide solution of the metals in said ore, and thereupon precipitating the dissolved metallic compounds other than arsenic and antimony by mingling the same with an oxide of an alkali earth metal.

635793—October 31, 1899. F. W. Martino and F. Stubbs. *Process of treating ores containing precious metals.*

The treatment of ores or tailings containing the precious metals by finely dividing the ore, mixing it with calcium carbide, and moistening the mixture with water.

644770—March 6, 1900. R. W. Kennedy. *Solvent for leaching ores.*

A solvent for leaching ores, comprising sodium thiosulphate, ammonium carbonate, copper sulphate, and potassium cyanide in water.

647989—April 24, 1900. T. Ryan, Jr., and N. Hughes. *Process of extracting zinc from substances containing same.*

The process of extracting zinc from substances containing the same, consisting in subjecting the raw material to the action of a solution of a caustic alkali, precipitating any lead present by galvanic action, securing the removal of organic matters and iron, manganese, and silicon by the addition of caustic lime and bleaching powder, and finally precipitating the dissolved zinc in the form of zinc oxide or zinc hydroxide by decaustifying the solution by the addition of an acid.

648354—April 24, 1900. C. G. Collins. *Process of extracting metals from their ores.*

The process of extracting metals from their ores, consisting in dissolving out or extracting the metal from the powdered ore by means of a solution of ammonium salt in the presence of an alkali base capable of decomposing the ammonium salt, and then precipitating the metal by the addition of a solution of an alkali metal.

652072—June 19, 1900. G. de Bechi. *Treatment of ore.*

The method of treating complex ores, consisting in subjecting the ore to a chloridizing roasting, condensing the vapors and gases evolved, treating the roasted ore and the acidulated water containing the condensed vapors and gases with calcium chloride to precipitate soluble sulphates and sulphuric acid as insoluble calcium sulphate, then lixiviating the ore with the acidulated water to obtain a solution of zinc and copper salts and fractionally precipitating zinc and copper from the said solution as hydrated oxides by successive additions of lime.

652849—July 3, 1900. S. H. Johnson and H. L. Sulman. *Process of extracting metals from ores or slimes.*

The method of treating pressed slime cakes containing residual water, which consists in displacing the residual water with an equal volume of a solvent solution, mixing the cakes with a further quantity of solvent solution, removing the metal bearing solvent solution by pressure, displacing the remaining portion of such metal bearing solution with water and extracting the metal from said metal bearing solution, whereby all the operations may be performed with an approximately constant volume of the solvent solution.

653414—July 10, 1900. E. Fink. *Process of extracting copper or other metals from tailings or ores of such metals.*

The process of extracting copper and other metals from tailings or ores of such metals, which consists in subjecting the tailings or ore to the action of a solution containing sulphuric acid and to the action of an oxide or oxides of nitrogen in the presence of air or oxygen under pressure, whereby the metal is oxidized and dissolved and the oxide or oxides of nitrogen are converted alternately into a lower and a higher oxide or oxides, and finally separating the solution from the earthy matter of the tailings or ore and separating the metal from the solution.

654804—July 31, 1900. G. Rigg. *Process of obtaining oxide and carbonate of zinc from materials containing zinc.*

The process of producing oxide of zinc and carbonate of zinc from zinciferous material, which consists in leaching the zinciferous material with a solution of ammonia and carbon dioxide wherein the carbon dioxide is in such proportion to the ammonia as to impart to the latter an approximately maximum zinc dissolving capacity.

656497—August 21, 1900. G. de Bechi. *Process of treating zinc bearing complex ores for recovery of zinc or other metals therefrom.*

The method of treating complex zinc ores for the recovery therefrom of copper, zinc, and lead, consisting in separately roasting the ore and an alkali chloride in the presence of air and steam, conveying the sulphurous and sulphuric vapors thus derived from the ore over and in contact with the said chloride during the roasting to obtain hydrochloric acid fumes, condensing the acid fumes, lixiviating the roasted ore with the acid liquor thus obtained to produce a solution of metallic chlorides, and successively precipitating the metals of the metallic chlorides as hydrates by successive additions of alkali.

656544—August 21, 1900. H. Hirsching. *Process of treating gold and silver ores.*

The process of treating copper ores, which consists in adding the comminuted ore gradually under agitation to an ammoniated solution, and then adding a diluting liquid to the mixture to obtain a highly concentrated copper solution.

657955—September 18, 1900. H. Petersen. *Process of enriching metallic sulphides.*

The process of enriching metallic sulphides, which are mixed with carbonates of the alkali-earth metals, consisting in dissolving out the carbonates with an aqueous solution of sulphurous acid.

659338—October 9, 1900. C. G. Collins. *Process of extracting zinc and copper from their ores.*

The process of treating ores of copper and zinc, which consists in immersing the comminuted ore in a solution containing sodium sulphate and bisulphate (niter cake), removing the depleted ore and extracting the metal therefrom by electrolytic action, adding more comminuted ore to the remaining solution, and repeating the operation.

659339—October 9, 1900. C. G. Collins. *Process of extracting copper and zinc from their ores.*

The process of treating ores of copper and zinc containing other metals soluble in any excess of solution which may be employed above that required to dissolve the copper and zinc contained therein, which consists in introducing the comminuted ore into a solution of sodium sulphate containing hydrochloric and sulphuric acid (salt-cake solution) not exceeding 5° Baumé, and subsequently recovering these metals from the solution.

659670—October 16, 1900. C. J. Head and R. C. Wild. *Method of treating telluride ores.*

A process for the extraction of tellurium from telluride auriferous ores and the preparation thereby of said ores for the better extraction of the precious metal therefrom, consisting of a lixiviation and digestion of the said ores in a solution containing about 5 per cent of caustic potash or soda for a lengthened period of two to six hours, the withdrawal of the solution after such digestion from the said ores, and the recovery of the tellurium from the solution.

660013—October 16, 1900. C. J. Head and R. C. Wild. *Method of treating telluride ores.*

A process for the extraction of tellurium from telluride auriferous ores and the preparation thereby of said ores for the better extraction of the precious metal therefrom, consisting of a lixiviation and digestion of the said ores in a solution containing about 5 per cent of carbonate of sodium or potassium for a lengthened period of two to six hours, the withdrawal of the filtrate, and the recovery of the tellurium from the solution.

663759—December 11, 1900. C. Hoepfner. *Process of producing solutions of zinc chloride.*

The process, which consists in reacting upon an oxide or insoluble salt of zinc in presence of water with sulphurous acid to form soluble zinc bisulphite, converting the bisulphite into a monosulphite by suitable reagents, mixing therewith its equivalent of sodium or potassium chloride and exposing the mixture to heat and air in the presence of a contact substance, such as oxide of iron, in order to convert the monosulphite into a sulphate, separating the zinc chloride from the solution and mixing therewith a sufficient quantity of an aqueous solution of sodium chloride to dissolve the zinc chloride and leave the alkali-metal sulphate practically undissolved.

678210—July 9, 1901. J. W. Worsey. *Process of treating complex ores.*

Process for the treatment of complex sulphide ores, comprising, first, the reduction of the combined sulphur below 15 per cent by calcination; secondly, finely powdering the calcined ore; thirdly, adding sodium nitrate; fourthly, boiling the mixed ore and nitrate in dilute sulphuric acid; fifthly, roasting the semisolid mass in a closed furnace; sixthly, dissolving out zinc copper and other soluble salts from the said mass by weak sodium-sulphate solution; seventhly, removing any copper from the solution; eighthly, precipitating the zinc and other metals from the solution; and, ninthly, separating the zinc.

679215—July 23, 1901. H. C. Bull. *Method of extracting gold from sea water.*

The method of extracting gold from sea water, which consists in mixing with a quantity of sea water a proportion of milk of lime to react upon the iodide of gold contained in the sea water to form iodide of calcium and to liberate the gold, then allowing the sludge formed by the reaction to settle, then drawing off the water and then collecting the sludge and treating it to extract the metallic gold therefrom.

683325—September 24, 1901. H. J. Phillips. *Extraction of precious metals from their ores.*

The method of extracting precious metals from refractory sulphide or telluride ores without roasting, which consists in subjecting the ore without roasting and in the form of a powder, under heat and pressure, to the action of alkaline polysulphides in solution of such weakness that same will have a selective action, namely, will dissolve the elements which are combined with the gold, and for which the polysulphides have a greater affinity than for gold, without dissolving the gold itself, which latter is thus dissociated and can then be recovered by any known suitable process for recovering free gold.

684578—October 15, 1901. C. W. Merrill. *Precipitant for recovering metals from solutions.*

The combination with a metal capable of precipitating other metals from cyanide solutions, if a gritty, inert, nonmetallic material, to increase the surface exposed per unit of weight of the precipitating metals.

689835—December 24, 1901. G. H. Waterbury. *Process of extracting copper from ores.*

The process of precipitating copper in solution, consisting in placing the solution in a tank or receptacle containing pieces of iron small enough to allow the solution to pass readily therethrough, and introducing hot air under pressure into the solution.

692008—January 28, 1902. O. Frölich, M. Huth, and A. Edelmann. *Separating process for ores.*

In the art of separating metals from ores containing iron among a plurality of metals existing therein in a combined form, the process, which consists in heating the ore to a temperature below the decomposition temperature of the sulphate of the metal to be sulphated, but above the decomposing temperature of the sulphate of any other metal existing in the ore, and then passing over it a gas mixture containing sulphur dioxide and oxygen.

693148—February 11, 1902. E. B. Parnell. *Process of treating ores.*

In the treatment of refractory ores, the process, which consists in subjecting them to the action of chromic acid and then roasting them.

695306—March 11, 1902. M. M. Haff. *Separation of the constituents of complex sulphide ores.*

The process, which consists in heating mixed sulphides of zinc and lead with sulphate of an alkali metal, treating the resultant mass with a dissolving agent to dissolve the zinc sulphate and alkali-metal sulphate, while leaving the lead sulphate undissolved, and adding barium hydrate to the mixed solution of zinc sulphate and alkali-metal sulphate to precipitate zinc hydrate and barium sulphate.

699326—May 6, 1902. T. A. Irvine. *Extraction of copper by the wet method.*

A process for the extraction of copper, consisting in the treatment of the ore within a mixed solution of chloride of sodium and sulphuric acid, in which solution there is an excess by weight of the chloride of sodium in respect to the sulphuric acid.

700311—May 20, 1902. F. Ellerhausen. *Treatment of complex and refractory ores.*

The process of treating complex and refractory ores containing lead, silver, and zinc, which consists in smelting the raw ores, churning the fumes and gases with water to condense and mix them with water, settling out the lead, silver, and part of the zinc compounds from the resulting liquor, as a sludge, separating and drying the sludge and fusing the sludge with caustic alkali, thereby precipitating the lead in metallic form.

702047—June 10, 1902. C. G. Collins. *Process of rendering metallic sulphides soluble.*

The process of rendering metallic sulphides soluble, consisting in drenching the crushed sulphide ore with aqueous ammonia, draining off the excess of aqueous ammonia, treating the ore thus moistened to an excess of oxygen, leaching the ore, and repeating the operation until the metal is all extracted from the pulp.

702153—June 10, 1902. J. P. van der Ploeg. *Treatment of ores and materials containing antimony.*

The method of extracting antimony from ores, materials, or residues containing it, consisting in finely pulverizing the material, mixing it with a suitable quantity of powdered quicklime, and then mixing with it an adequate quantity of sulphide of an alkali-earth metal and water, so as to form a solution of the lower and most soluble double sulphides as being the best electrolytes, without the use of artificial heat or application of pressure.

702244—June 10, 1902. A. J. Polmeteer. *Precipitant for treatment of copper water.*

The precipitant for copper water, containing in solution a sulphide and an excess of alkali.

702582—June 17, 1902. J. W. Neill and J. H. Burfeind. *Process of recovering metals from ores.*

The improvement in treating copper or other ores, consisting in agitating a charge of pulp containing the ore by gas from roasting furnaces charged with material suitable for producing sulphurous-acid gas, separating the resultant solution, precipitating the metal from the solution, thereby releasing gas and employing the sulphurous-acid gas released by the precipitating process to enrich the gas derived from the furnace and used in leaching a charge of ore.

704640—July 15, 1902. C. Hoepfner. *Process of extracting copper and nickel from sulphide compounds.*

The process, which consists in oxidizing roasting copper and nickel sulphide ores or mattes, leaching the sulphate of copper formed, converting this into cupric chloride and then into cuprous chloride, dissolving the nickel salts in the residue by said cuprous chloride, precipitating cuprous chloride from the solutions formed and returning the resulting solution containing some cuprous chloride into the cycle of operations.

704641—July 15, 1902. C. Hoepfner. *Process of extracting zinc or other metals from their ores.*

The process, which consists in reacting on a material containing an oxygen compound of metals insoluble in water and whose chlorides are soluble in a solution of alkali metal chloride, with sulphurous acid and an aqueous solution of alkali metal chloride, whereby a solution is formed containing a chloride of a metal.

706302—August 5, 1902. L. B. Darling. *Means for extracting precious metals from ores.*

In a gold extracting plant provided with a substantially flat treating floor of nonabsorbent material, a series of longitudinally extending channels formed therein, a transverse groove or end launder in direct communication with said channels, fixed screens or strainers covering the top of said channels and launder, side launders or ducts, and valved connections interposed between and uniting the said end and side launders.

707107—August 19, 1902. J. Herman. *Process of treating ores.*

The process, which consists in roasting sulphide of copper ore at a low heat to form sulphates of the copper and some of the iron present, and produce a large percentage of ferrous sulphate, leaching the roasted ore, precipitating the metallic copper, and adding salt to the leaching solution before or after the precipitation of the metallic copper, whereby the ferrous salts in the solution are converted to the chloride, and a solution having an excess of salt is produced, and the said solution is adapted to dissolve copper and silver out of carbonate and oxide ores.

707506—August 19, 1902. E. Ferraris. *Method of treating mixed sulphide ores.*

The process of decomposing mixed sulphide ores by means of concentrated sulphuric acid without the aid of extraneous heat.

709037—September 16, 1902. W. Pethybridge. *Treatment of telluride gold ores.*

In the decomposition of ores containing telluride of gold, the process of reducing the ore to a finely divided state and then exposing the ore to the action of a solution of ferric chloride alone to attack the tellurium.

715023—December 2, 1902. J. C. Clancy and L. W. Marsland. *Process of treating zinc sulphide ores.*

In extracting metals from zinciferous sulphide ores, roasting pulverized ores with the addition or admixture of lead sulphate obtained from a source external to the ore being treated in quantity proportional to the quantity of zinc the ore contains.

715771—December 16, 1902. F. Ellerhausen and R. W. Western. *Treatment of zinc ores.*

The process for the treatment of zinc ores and other zinciferous matter, consisting in calcining where necessary, wetting with a dilute solution of ammonium sulphate, adding sulphuric acid, washing with ammonium sulphate, and precipitating with aqueous ammonia and heating the precipitate.

715804—December 16, 1902. H. E. Howard and G. Hadley. *Treatment of spent acid from galvanizing works.*

The treatment of spent acid from galvanizing works by adding zinc thereto, separating the solution from the precipitate, treating with bleaching powder to transform the ferrous salts into ferric salts, then adding alkali to precipitate the iron present as ferric hydrate, and subsequently more alkali for the precipitation of the zinc salts.

716847—December 23, 1902. F. W. Martino. *Treatment of ores containing precious metals.*

The process of separating gold from ores containing tellurium, selenium, sulphur, arsenic, antimony, tin, phosphorus, or the like, consisting in grinding the mixture, heating it with powdered barium sulpho carbide in a reducing (muffle) furnace, dissolving out the soluble sulphides thus formed, treating the solid residue with a gold solvent, and precipitating the gold therefrom by the employment of barium sulpho carbide.

717299—December 30, 1902. G. C. Stone. *Extraction of zinc and lead from sulphide ores.*

The method of separating zinc and lead from sulphide ores, which consists in smelting the sulphides, oxidizing the volatile constituents at their exit from the smelting furnace, cooling the resulting fumes and products of combustion to a temperature not exceeding 180° F., and passing them into contact with a solvent which will dissolve out one of the metals and not the other.

717565—January 6, 1903. A. von Gernet. *Process of extracting copper from its ores.*

The process of extracting copper from its ore, which consists in slowly passing the ore in the form of pulp through a current of sulphurous acid, passed in a direction opposite to that of the travel of the pulp.

717864—January 6, 1903. J. T. Jones. *Method of treating ores.*

The process of mixing with ore, to be treated, a leaching fluid, which consists in confining the mass of ore in a vessel with a body of leaching fluid of lesser specific gravity superimposed upon it, carrying portions of the ore upward in said vessel and releasing it above the body of leaching fluid, to precipitate it through said body and simultaneously convey portions of the leaching fluid below the surface of the mass of ore and releasing it, and permitting it to rise through the same.

718099—January 13, 1903. S. C. C. Currie. *Method of reducing ores.*

The step in the art of treating pulverized ores containing precious metals, which consists in subjecting the ore, in a closed vessel, to the action of hot air at a temperature which reduces some of the salts in the ore from an insoluble to a soluble condition in water, then washing away the soluble salts with water and then repeating the step with air at a higher temperature.

719132—January 27, 1903. W. Payne, J. H. Gillies, and A. Gondolf. *Process of treating copper ores.*

The process of treating copper ores, consisting in first roasting to an oxide, next saturating the same with a solution of ferrous sulphate or sulphate and chloride, next roasting again and meanwhile adding a small percentage of iron sulphide or sulphur,

according to the percentage of copper present, and finally leaching the hot ore.

719757—February 3, 1903. S. C. C. Currie. *Process of treating ores containing precious metals.*

The method of treating ore, which consists in heating the raw pulverized ore in contact with steam, and plunging the heated ore into an aqueous alkaline solution.

723787—March 24, 1903. S. Trivick. *Process of extracting metals from ores.*

A process for evolving nascent chlorine and effecting the chlorination of metallic substances in order that they may be extracted from a metalliferous mass by rendering them solvent, consisting in adding to the mass a mixture in definite proportions of two substances, one being dry chloride of lime and the other ferric sulphate, the proportions being such as to result in the formation of ferric hypochlorite and ferric chloride which will evolve nascent chlorine.

723949—March 31, 1903. G. D. Van Arsdale. *Process of separating copper from ores.*

The process of extracting copper from ores, or products containing copper, which consists in separating copper from cupric-sulphate solutions, with or without ferrous or other suitable sulphate, and of simultaneously producing free sulphuric acid, by adding to such solutions sulphur dioxide and heating with or without pressure, whereby copper or copper compounds are thrown down in the solid form to be subsequently treated, and free sulphuric acid is formed, and of adding the acid liquors thus obtained, after separation from the copper precipitate, to copper ores, whereby the copper contained in them is dissolved and the original solution regenerated and the process repeated and thus made continuous.

724414—March 31, 1903. G. H. Waterbury. *Copper leaching process.*

The copper leaching process, consisting in placing the suitably pulverized ore in a leaching tank, adding water, acid, common salt, and oxide of manganese in suitable quantities, heating the mass by the introduction of steam to a suitable temperature, and finally subjecting the pulp to agitation during a suitable period.

725257—April 14, 1903. T. B. Joseph. *Gold extraction process.*

The process of extracting precious metals from ore containing the same, when in a suitable condition, which consists in subjecting the said ore to a leaching action of a solution of water, cyanide of potassium, hydrate of calcium, carbon dioxide, and bromine, and subsequently precipitating the precious metals from the solution.

725548—April 14, 1903. H. R. Ellis. *Process of extracting copper from carbonate and oxide ores.*

The process of extracting and recovering copper from its carbonate or oxide ores or from material carrying carbonates or oxides of copper, which consists in subjecting the ore or other material in a crushed or powdered state to the action of a carbonate of soda or its described equivalents until the copper is dissolved and subsequently subjecting the charged solution to electrolytic action.

726802—April 28, 1903. B. T. Nichols. *Ore treating process.*

The process for treating ore preparatory to leaching, consisting first in mixing the suitably pulverized ore with lime; second, applying water to the mixture and introducing steam whereby the pulp is agitated and kept at a suitable temperature until certain impurities which retard leaching are freed; third, washing the pulp by the introduction of water and continued agitation; fourth, draining off the water as far as practicable; and, finally, drying the ore.

729760—June 2, 1903. G. V. Gusman. *Process of reducing and separating silver.*

The process of extracting and separating silver from its ores, which consists in subjecting roasted ores to the action of a preprovided aqueous solution of cupric chloride and cuprous chloride, passing the resulting solution through granulated metal, and removing and collecting the metallic silver from said metal.

729819—June 2, 1903. J. F. Webb. *Apparatus for use in extracting metals from ores.*

A tank for use in extracting metals by chemical process from their ores, having a filter bottom and means for discharging air within the tank and downwardly upon the said bottom, whereby the said bottom is kept free from clogging and air is supplied to agitate the mass within the tank and supply oxygen thereto.

734683—July 28, 1903. J. F. Duke. *Process of obtaining gold from sea water.*

The process of obtaining gold from sea water containing the same, which consists in precipitating the gold by carbonate of calcium.

735098—August 4, 1903. C. Hoepfner. *Process of obtaining lead or other metals from ores or mattes.*

The process, which consists in leaching compounds containing lead and iron with a solution of cupric chloride containing a solvent of the chlorides of said metals, supplying oxygen to produce oxychloride of copper whereby the iron is precipitated, and precipitating the lead as a sulphite by means of a sulphite of zinc.

735512—August 4, 1903. H. Hirsching. *Treatment of ores containing gold, silver, copper, nickel, and zinc.*

The process for extracting gold, silver, copper, nickel, and zinc from substances containing the same, which consists in subjecting said substances to the action of an acid, washing with water the substance thus treated, thereby forming solutions containing compounds of gold and base metals, and then subjecting said solutions to the action of ammonia for the purpose of precipitating the gold and recovering the base metals from the solution separately, and also the ammonia.

739011—September 15, 1903. F. Laist. *Process of treating ores.*

The method of generating hydrogen sulphide and precipitating copper, which consists in subjecting an alkaline-earth sulphide in presence of water to the action of carbon dioxide, thereby generating hydrogen sulphide and precipitating the carbonate of the alkaline-earth metal, conducting said hydrogen sulphide into the presence of copper in solution, thereby precipitating copper sulphide and forming a solvent liquid, treating copper ores with said solvent liquid, and collecting said alkaline-earth carbonate and reconverting it into sulphide.

740014—September 29, 1903. J. Herman. *Process of treating ores.*

A process of extracting copper from ores, which consists in treating ore containing iron to produce ferrous chloride, utilizing the chloride and free acid to dissolve carbonates and oxides of copper, the free acid being adapted to neutralize interfering substances and to attack the surface of the particles of copper oxide or carbonate, and regenerating the free acid by the electrolytic precipitation of copper.

740372—September 29, 1903. C. Rogers. *Process of extracting zinc from sulphide ores, etc.*

The process for the extraction and recovery of zinc from zinc containing sulphide ores or tailings, which consists in subjecting the same to a partial sulphatizing roast, discharging the same while hot into water, leaching the same with said water and with dilute sulphuric acid, subjecting the leached ores or tailings to a second sulphatizing roast, releaching the same with the lixivium from the former leaching, and repeating said operations until sufficient zinc and sulphur are removed.

740701—October 6, 1903. A. M. G. Sebillot. *Treatment of sulphide ores.*

A process for treating ores containing sulphur consisting of sulphating the ore in a closed vessel by the action of sulphuric acid upon the metallic sulphides at a temperature above its boiling point and simultaneously recovering the sulphuric acid used, cal-

cining the sulphated ore at a temperature of 700° Centigrade to dissociate the sulphate of iron to prevent dissolving of a too great quantity of sulphate of iron in the lixiviating liquors, and then lixiviating the calcined ore.

748662—January 5, 1904. A. M. G. Sebillot. *Process of treating copper ores.*

The process for extracting pure metals from mineral ores, consisting in treating the ores with sulphuric acid at the evaporating point of the latter, without roasting, to form sulphates, condensing the surplus acids fumes, and lixiviating the sulphates in successively deeper baths under constant agitation, in a current flowing in direction opposite to the progress of the ores.

749700—January 12, 1904. P. Naef. *Process of lixiviating ores.*

The method of lixiviating ores or other pulverulent materials, which consists in passing the ore downward in thinly divided layers through an ascending stream of leaching solution and at the same time passing a current of air or gas repeatedly through the ore layers in numerously divided jets, whereby the ore particles are agitated in the solution, and the same volume of gas acts successively as an agitating medium.

752320—February 16, 1904. J. B. de Alzugaray. *Extraction of metals from complex ores.*

In the treatment of complex ores, such, for instance, as contain copper, lead, silver, and zinc in comparatively large quantities, the process of extracting the said metals selectively, which consists in leaching the ore with a solution composed of a mixture of a chloride of an alkali or earth-alkali metal with a chloride of a metal other than those of the alkali or earth-alkali series and an acid before calcination or roasting whereby the copper is obtained in solution, then washing and drying the ore, roasting the partially disintegrated ore at a low temperature, extracting the metals from the roasted ore in form of salts by means of a second and weaker leaching solution having a character consonant with the nature of the salt it is desired to obtain, and recovering the metals in the usual way.

754643—March 15, 1904. K. Danziger. *Process of separating iron pyrites from zinc-blende.*

A process for separating iron pyrite from zinc-blende, which consists in exposing the zinc-blende to the action of air moisture and heat, and extracting the ferrous salt which has been formed by the oxidizing action by water.

755871—March 29, 1904. T. A. Helm. *Apparatus for treating ore.*

An apparatus for treating pulverized auriferous ores, comprising a rotatable cylindrical tank, radially depending blades in the tank extending the length thereof, a circular brace-frame disposed between the inner ends of the radial blades, an air pipe leading into the tank, faucets to draw off a liquid from the tank, and means to rotate the tank.

CLASS 75.—METALLURGY.

Subclass 86.—Solution and precipitation—Apparatus.

108158—October 11, 1870. W. S. Laighton. *Improvement in apparatus for precipitating gold and silver from solutions.*

The invention consists in combining two vessels—one to receive the solution to be precipitated and the other the precipitant—and connecting them by an automatic apparatus that shall deliver a certain quantity of the precipitant into the other vessel every time it is filled and provide for the discharging of the same, the quantity of the solution that receives the precipitant, measured out, being governed by a hydrometer or hydrometric float, which is used to operate the apparatus.

213382—March 18, 1879. C. C. Bitner. *Improvement in apparatus for obtaining metallic copper from its solution.*

The invention relates to a novel apparatus for obtaining metallic copper from its solution; and it consists in the employment of a tank or vat having a horizontal perforated diaphragm, upon which is placed a quantity of iron. This tank is filled with a solution of copper, previously prepared from the roasted ore in the usual manner. Through the top of this tank a steam pipe passes and extends below the diaphragm, so that the solution is heated by this injected steam, and, by the motion which its action gives, the deposition of the copper is hastened. By means of peculiarly arranged slides the steam is admitted above the diaphragm through holes in the steam pipe to assist the process, if desired.

234073—November 2, 1880. R. Schulder and E. H. Russell. *Ore-leacher.*

The invention consists of a circular frame supporting the filter and moving on a circular track above an inclined circular table; and it consists, further, of three stationary rollers, designed to elevate and depress the filter at certain points as it revolves, of a device for feeding the substance to be leached upon the filter, of a device for applying the leaching solvent, and of a precipitating tank to contain the solution passing through the filter.

248768—October 25, 1881. J. F. N. Macay. *Filter.*

The invention relates to improved apparatus for use in effecting the operations of dissolving solids in liquids and producing chemical reactions, and of filtering or separating liquids from solids in chemical and metallurgical processes, in which a soluble substance or substances, mixed or combined with an insoluble substance or substances, is or are to be dissolved separately or together, wholly or partially, in a given solvent or solvents, and the solution separated by filtration from the undissolved residue.

In effecting the separation of liquid from solid matters by filtration it is of importance to keep the filtering surface from being clogged by the particles of solid matter, and to present a clear and unobstructed filtering surface for effecting the rapid separation of the liquid from the solid matters. In the apparatus of the invention this important condition is realized in a very effective manner, the construction and operation of the apparatus being as follows:

Within a cylinder of wood or other material not chemically acted on by the materials treated or the reagents employed is inclosed an inner cylinder of hard wood, or of hard earthenware or stoneware or other material not chemically acted on by the materials treated or the reagents employed, this inner cylinder being perforated with holes and lined internally or externally, but preferably internally, with asbestos cloth or other suitable filtering material.

Between the inner and outer cylinder there is an annular space, and the inner cylinder is kept in place by longitudinal and circumferential partitions, the former of which divide the annular space into a number of distinct compartments, each provided with a draw-off cock for running off the liquid when separated by filtration. This cylinder is capable of being rotated, and is provided with doors or manholes in one of the heads by which the matters to be treated may be introduced and the undissolved residue removed; and the cylinder is also provided with a tubular journal or journals for the introduction of steam, water, air, or other liquids or gases, under pressure or otherwise, which may be blown, forced, or drawn into the annular space for the purpose of keeping the filtering surface clear and of acting chemically or mechanically upon the contents of the cylinder. I place within the inner cylinder the ore or other matter to be treated (previously ground or otherwise reduced to a pulverulent state), together with the reagents or solvents by which it is to be treated. By imparting rotary motion to the cylinder (the draw-off cocks and manholes being closed) the solid matters are brought into intimate contact with the solvents or reagents, and by forcing steam, water, air, or other liquids or gases into the space between the inner and outer cylinders, and thence through the filtering medium into the inner cylinder, any solid matters that may adhere to the filtering surface are disengaged therefrom, whereby the said surface is kept clear, the solid matters are kept in suspension in the liquid, and chemical action, which the liquid or gaseous reagents may be capable of exerting on the said matters, takes place under the most favorable circum-

stances as regards the intimate mixture of the reagents with the matters and the large surfaces exposed to their action. The annular space between the inner and outer cylinders being divided into compartments by longitudinal divisions, the liquid which passes through into it is carried round by the rotation of the cylinder and flows back into the inner cylinder, thus helping to keep the filtering surface clear and unobstructed. When the soluble substances are dissolved or chemically acted upon, and it is desired to separate the liquid from the solid matters, the draw-off cocks are opened, and then, by giving a slow rotary motion to the apparatus, the liquid may be decanted off from the bulk of the solid matter and at the same time filtered from any such matters which it may hold in suspension by passing through the filtering medium. By this rotary decanting action a practically clear filtering surface, unobstructed by solid matter, is constantly presented for the liquid to pass through.

251718—January 3, 1882. A. E. Jones. *Apparatus for separating gold from quartz and rock tailings.*

The invention consists in the arrangement and application of a suitable fibrous material in combination with machinery, so that the fibrous material will unite or collect to itself the gold and carry and deposit the same to a place designated, where it may be collected and treated as desired in separating the precious metal from its sand and ore. Any fibrous matter that will form a pulp when mixed with water is used to coat a wire-cloth screen as in paper making, and then entangle the fine gold in suspension in the water.

301460—July 1, 1884. J. L. Russell. *Slime filter.*

The invention consists of a trough containing at intervals within it a series of double filtering boxes covered with wire gauze and filled with charcoal, sponge, or any known filtering substance, and the claims cover the trough poised over filter sections provided with adjustable partitions, as well as the combination of a sand box, a sluice provided with adjustable partitions, filters composed of frames and wire gauzes, and gutters.

325835—September 8, 1885. H. C. and J. A. Henderson. *Apparatus for concentrating ores.*

The apparatus for concentrating ores, consisting of an outer tank, an inner filtering tank, provided with fabric ends, and a perforated feed box having its lower end below the top edge of the tank, a space being left between the sides, ends, and bottom of the tanks whereby, when the water is received by the perforated feed box, it will pass into the inner tank and slowly filter through the fabric ends thereof and flow over the top edge of the outer tank, the fabric ends preventing the formation of a current and causing the particles of ore to be precipitated.

366103—July 5, 1887. O. Hofmann. *Process of extracting silver from its ores by lixiviation.*

The invention relates to a certain improvement in the lixiviation process by which the ore, after having been subjected to a chloridizing roasting, is introduced in a series of troughs, first, together with water to dissolve the base-metal chlorides, and, second, together with the solution used in the ordinary lixiviation process to dissolve the silver. The ore and water are introduced either by means of a mixing box or an agitator, and are allowed to flow in these troughs for some distance, and finally conveyed by them into settling tanks. The water while running in the troughs dissolves the base-metal chlorides. In the settling tanks the ore separates quickly from the liquid. The latter is drawn off and conveyed to other tanks for the usual treatment. The ore sediment containing the silver is now sluiced or charged again in a similar series of troughs with a solution which has the property of dissolving chloride of silver, like hyposulphite of lime or soda, concentrated salt solution, Russel's "extra solution" (a compound of hyposulphite of lime or soda and bluestone), etc. By passing through this second series of troughs the silver chloride dissolves. Ore and solution run into tanks which are provided with filter bottoms and allowed to separate. The tailings settle to the bottom, while the clear solution, now containing the silver, is drawn off and conveyed into the precipitation tanks for the usual treatment.

370871—October 4, 1887. F. F. Hunt. *Apparatus for agitating solutions in the leaching of metals from their ores.*

The invention relates to an improvement in apparatus for agitating the acid solutions formed in the leaching of copper and other ores; and the object of the same is to provide a form of rotary agitator in which the heavier portions of the charge can not accumulate at the center of the apparatus and escape the action of the agitating arms, which will also produce a more perfect agitation of the solutions than has heretofore been possible, and which will be more durable and economical to construct than the forms in present use.

Heretofore the agitators used in leaching works have usually been made with flat bottoms and have been provided with stirring or agitating arms of conical shape at the base, arranged to rotate a slight distance above the bottom. In the invention this arrangement is reversed, and the agitating tank is constructed with a cone of small altitude placed apex upward in the center of the bottom and covering a considerable portion thereof, and is provided with agitators, the arms of which are provided with concave shoes and are arranged to rotate in close proximity to the cone in the bottom of the tank.

412610—October 8, 1889. J. B. Hannay. *Apparatus for applying chlorine to the extraction of gold from ores.*

This invention relates to means of extracting from ores precious metals, especially gold, in the form of chloride solution. For this purpose an apparatus is employed which consists of a chlorinating vessel, a set of circulating pumps, a filter press, and a chlorine pump, or sets of these, with suitable communicating pipes, cocks, and valves for operating in the following manner: Having reduced the ore to a fine powder, it is mixed with water or with chlorinated water to a condition of thin sludge, which can be pumped. Then charge the chlorinating vessel with this sludge and apply the pumps to cause its circulation therein, drawing from the upper part and discharging into the lower part, while chlorine gas is pumped into the vessel, preferably to a pressure considerably above that of the atmosphere. After circulation has gone on for some time, until the metal in the ore is mostly dissolved by the chlorine, the sludge is pumped by the circulating pumps into the filter press, additional pressure being given, if required, by using the chlorine pump to force air into the upper part of the chlorinating vessel. The liquid issuing from the filter press containing in solution the metallic chloride is treated in any of the known ways for separating the metal and recovering the chlorine. In some cases the solution discharged from the filter press may be used in a subsequent operation to form the sludge by its admixture with a fresh quantity of pulverized ore, and this may be done repeatedly, so as to obtain finally a filtered liquor rich in chloride.

As it is advantageous to charge the chlorinating vessel with an excess of chlorine above that which enters into combination with the metals, the inventor prefers to collect such excess before discharging the sludge by blowing in a little steam to warm the sludge and allowing the free chlorine thus liberated to pass either into a gasometer or into another chlorinating vessel; or an exhaust pump may be employed to draw off the free chlorine.

When metals such as silver are present, having insoluble chlorides, the blocks which are taken from the filter press, and which contain these chlorides, may be reduced to sludge, as before mentioned, and may be subjected to the same treatment with a suitable solvent instead of the chlorine.

418138—December 24, 1889. J. S. MacArthur. *Metallurgical filter.*

A metallurgical filtering apparatus for separating a precious metal from a solution containing said metal, consisting of a series of vessels, each of which has an inlet tube near its bottom, an out-

let tube near its top, and a perforated false bottom above the inlet tube, zinc sponges disposed in the several vessels, pipes connecting the inlet and outlet tubes of the several vessels, and a reservoir for supplying the solution to the first vessel of the series.

425025—April 8, 1890. D. Dennes and T. K. Rose. *Apparatus for leaching ores.*

In a leaching apparatus, a movable table, having a flange or wall projecting from its upper surface to form a receptacle for filtering material, the said receptacle being of less diameter than the upper surface of the table, whereby a packing receiving ledge projects beyond the base of the said wall or flange, combined with the leaching cylinder, the lower end of which is constructed to receive said wall or flange, while the ledge abuts against said lower end of the cylinder.

442262—December 9, 1890. S. Trivick. *Apparatus for treating ores to obtain precious metals therefrom.*

This invention relates to improvements in apparatus forming a plant for treating roasted ground ores to obtain precious metals therefrom, adapted for use in treating roasted ground ores of precious metals that have been roasted by any known or suitable method.

The apparatus consists, essentially, of a vessel (preferably employing a pair at least of such vessels, so as to change from one to the other of the pair in working) having a porous bottom on which the ground roasted ores rest; means of supply of leaching liquid controlled by valve; means of drawing off leached liquid, conveyance thereof to, and means of stirring said liquid in a mixing chamber—a filter vessel having a porous floor—and means of pumping the filtered liquid to a reservoir; means of evaporating the leaching liquor to recover the contained salts; also recovering the copper salts for reuse, and means of heating the leaching liquid, and also means of desiccating the product.

The invention also consists in a furnace for roasting ores of precious metals, comprising, among other features, a chamber, coils of piping, a tank, reservoir, a force pump, a system of heating pipes, leaching reservoir, tanks with porous floors, and a mixing vessel with rotating stirrers therein.

449813—April 7, 1891. J. Cragg. *Apparatus for extracting gold or silver from ores.*

In an apparatus for extracting gold or other metals from their ores in solution, a tower and a mixer, which consists of a trough having pipes to conduct the reagents in liquid solution, which enter the same from different sides and terminate out of alignment about centrally of the trough, combined with a hopper placed over the ends of the said pipes and an overflow plate leading to the said tower.

456323—July 21, 1891. P. L. Gibbs. *Ore leaching machine.*

This invention has reference to ore leaching machines in which a rotating annular series of ore receptacles pass successively under an ore vat containing the crushed ore in a solution to receive their respective contents or to be otherwise filled, and to discharge the filtrate during their transit into a suitably placed discharging conduit or launder and at a predetermined point in their orbital movement and automatically discharge the residuum.

The objects of this improvement are, first, to provide a suitably suspended vat to receive the ore in a solution, or dry or roasted ore, and adapted by suitable openings in the bottom thereof to optionally discharge said contents; second, to provide a series of leaching vats to pass successively under said primary vat and respectively receive from the latter a proper quantity of its contents; third, to provide suitable mechanism for supporting and progressing said secondary vats; fourth, to provide a conduit or launder to receive and carry off the filtrate from said leaching or secondary vats; and, fifth, to afford facilities to automatically discharge the residuum from said leaching vats preparatory to their refilling.

463120—November 10, 1891. D. Dennes. *Leaching vat for separating precious metals from their ores.*

An ore leaching apparatus consisting of a closed vat or separating vessel having a removable bottom carrying a filter bed in its upper portion and an auxiliary chamber beneath, provided with a removable bottom and a filter bed, and a suitable pipe connection between the separating vessel and said auxiliary chamber in its bottom.

464672—December 8, 1891. W. D. Bohm. *Apparatus for separating gold and silver from ore.*

The inventor places the powdered or divided ore, or material to be treated for the obtainment of the gold or silver, or both, in a vessel or vat, or vessels or vats, and through it passes the leaching solution, preferably previously heated. By means of a force pump, the leaching solution is forced up through the ore and through a filter at the top. The solution and the precious metal which it now contains pass into a vessel in which it is agitated with a precipitating agent. From this last-named vessel the solution is forced up by a force pump through a vessel having a filtering arrangement, such as a porous diaphragm, at the top, so that the solid matter is retained thereby, the liquid passing off to be heated again and to be restrengthened by the addition of the necessary further quantity of leaching chemicals and passed back to the leaching vat or vats for reuse. The pressure under which the liquids are forced up through the leaching vat and precipitant vessel should be at least eighteen pounds per square inch. At intervals the solid matter retained by the last-named filtering vessel is passed into a filter press or equivalent apparatus, whereby it is deprived of the greater part of its moisture. The ore which has been leached is then drained of all solution and washed free from the last traces thereof with water, preferably hot, and then can be washed out of the vat or vats with acidulated water, and passed over zinc or alloy of zinc with other suitable metal, so that hydrogen is evolved, which reduces any precious metal still remaining in the ore to the metallic state, or such state that it is taken up when the ore is afterwards passed over mercury—for instance, over amalgamated copper.

495385—April 11, 1893. F. Webb. *Method of and apparatus for extracting precious metals from their ores.*

The inventor claims, in means for extracting precious metals from their ores, the combination of an outer vessel resting in suitable trunnions for containing the reagent or chemical solution, and having inlet and outlet pipes communicating, respectively, with the top and bottom thereof through said trunnions, a perforated vessel in said outer chamber, and adapted to receive the crushed ore, and provided with a manhole opening extending to the outside of the latter, and means for reciprocating the inner vessel and for rotating the outer vessel on its trunnions, whereby the contents of the inner vessel may be discharged. Also, the method of separating precious metals from their ore, consisting in placing the disintegrated or crushed ore in a closed perforated vessel and causing the latter to reciprocate in the reagent or chemical solution, whereby the latter is enabled to more effectually act upon the ore.

497856—May 23, 1893. C. G. Brown. *Ore tank.*

In a tank for leaching or saturating ore, the combination with a false bottom and a piece of textile material laid upon the upper side of said false bottom; of a series of vertically disposed perforated tubes designed and adapted to hold the pieces of ore apart and promote the circulation of the leaching or saturating solution.

525970—September 11, 1894. J. Storer and B. T. Lacy. *Method of and apparatus for dissolving, leaching, and filtering.*

The inventor claims the improved method of dissolving, leaching, and filtering, consisting, essentially, in connecting a plurality of closed tanks in series, then introducing an expansible medium upon a body of noncompressible fluid contained in a terminal tank to force the said fluid under pressure into the successive tanks

and through the material under treatment until it reaches the final tank, then connecting this last-named tank with the initial tank, and finally introducing pressure in the said final tank to force the fluid therefrom so that it may be returned to said initial tank. And in an apparatus for dissolving, leaching, and filtering, the combination of the tank adapted to contain the material to be treated, a tank adapted to contain a noncompressible fluid and connected with a source of steam, gas, or vapor supply, a valve-controlled pipe from said fluid tank to said material-containing tank, a final tank beyond the material-containing tank, a valve-controlled pipe connecting said material-containing tank with said final tank, whereby the fluid is forced into said final tank, a valve-controlled pipe connecting said final tank with the initial fluid tank, and means for admitting an expansive medium into said final tank to force the fluid therefrom back into the initial tank.

530397—December 4, 1894. N. H. Cone. *Filter barrel.*

In an apparatus of the class described, the combination with a revoluble cylinder having a hollow trunnion, and a head provided with radiating channels having independent valves of a filter arranged in said cylinder and valves for opening or closing said channels independently of each other.

536981—April 2, 1895. T. L. Wiswall and J. B. Frank. *Receptacle for recovering precious metals from solutions.*

This invention relates to apparatus wherein the recovery of the precious metals from cyanide and other solutions is effected by passing the solutions through a filtering material, by which the precious metals are precipitated. And the inventor claims, in apparatus for the extraction of precious metals from solutions, the precipitating box, having an undulating, sinuous passage from end to end, comprising a series of alternate angular depressions and elevations, provided with a series of retaining pins, attached to the interior of said precipitating box, and extending into the precipitating, filtering material within said passage.

549177—November 5, 1895. T. L. Wiswall and J. B. Frank. *Apparatus for recovery of precious metals from their solutions.*

The inventors claim, in apparatus for the recovery of precious metals from their solutions a precipitating box adapted to contain a finely subdivided, metallic, precipitating reagent, divided into a series of compartments by removable perforated partitions, said partitions being provided with adjustable gates, controlling the flow of said solution through the perforations in said partitions for the purposes indicated.

549622—November 12, 1895. P. Argall. *Apparatus for extraction of precious metals.*

The specifications set forth that in the treatment of ores by the cyanide process to extract their gold and silver contents, it is the usual practice to place the ores in open leaching tanks and allow the cyanide solution to percolate through the mass and so dissolve and remove the precious metals in solution. This method is on the whole fairly efficient, but it occupies considerable time (forty to eighty hours) and causes a large consumption of cyanide through decomposition, owing to its long contact with the ore and atmosphere. With many classes of ore, however, it is found that agitation of the ore and solution is necessary in order to obtain the best results or largest extraction of precious metals. Particularly is this the case with silver-bearing ores or ores carrying considerable value in silver.

The agitators heretofore in use shorten the time necessary to dissolve the precious metals; but they invariably cause a large consumption of cyanide, due chiefly to the continuous agitation of the solution in open tanks or in partly filled barrels in the presence of an excess of air, while the ore when discharged from the agitators is in such a condition that very often it can not be leached, or at best but part of the cyanide solution containing the dissolved gold can be separated from the ores. Then again, the agitators now in use are of such small capacity as to add largely to the cost of treating the ores.

This invention relates to a new machine for treating ores by continuous agitation and continuous percolation under pressure or by means of vacuum and either with or without external or additional heat. And the inventor claims a percolator for treating ores by the cyanide process comprising an outer shell capable of being closed, air-tight, hollow trunnions upon which said vessel rotates, concentric tubes extending axially through the vessel, the outer tube being covered by a filtering medium, a passage connecting the annular space between the tubes with one of the hollow trunnions, and a pipe communicating with the chamber surrounding the outer tube. The invention includes other features of a minor or subsidiary character.

552807—January 7, 1896. H. G. Williams. *Method of and apparatus for extracting metals from their ores.*

In an apparatus for the extraction of precious metals from their ores by the wet process, the combination of one or more castings, with screw conveyers and mixers, means for feeding the solid and liquid matters thereto, and a dam placed at the discharge end of the casing for each conveyer, having its surface inclined upon the side next to the conveyer flights or blades, for the purpose of maintaining the admixture of the liquids and solids by preventing the liquid from traveling faster than the solid and still giving passage by reason of its incline to the travel of the solids over the same; and, in the extraction of precious metals from their ores by the wet process, the method of continuously and uninterruptedly precipitating and separating the metals, which consists in simultaneously introducing the precipitating agent and an independent agitating blast of steam into the solution of metal in direction as described to secure admixture and agitation by a whirling motion and the agglomeration of the precipitated particles of metal, and continuously separating the precipitate by settlement and filtration.

567144—September 8, 1896. S. B. Ladd. *Apparatus for leaching ores.*

The object of the present invention is to provide an economical and practical apparatus for the lixiviation of ores, and particularly applicable to cases where a large mass of material has to undergo treatment—as, for example, in the lixiviation of low-grade gold ores by the cyanide process—and where the expense of handling material becomes an important factor with respect to the commercial working of the process. The invention applies, generically, to the lixiviation of comminuted or pulverized material of any character, but it is especially designed for the lixiviation of ores by the cyanide process, for in the treatment of ore pulp or slimes by the cyanide and other like processes a large amount of material, often of a low grade, has to be subjected to the action of an aqueous solution of a cyanide or other solvent, or to the successive action of a series of solutions. The common course of procedure in working the cyanide process on a large scale is to run the ore pulp into large vats and then to cause the proper solutions for leaching out the precious metals to percolate therethrough, for example, first an alkaline solution, when the ore is acid, then a strong solution, then a weaker solution, and finally water to wash the pulp. The vat is then emptied and refilled with fresh ore pulp; also, the solvent process is sometimes worked by agitating the pulp and leaching solution in pans or vessels. Both systems require considerable labor and are intermittent.

Another object of the present invention is to provide means to make the extraction process continuous, so that the ore pulp shall progressively and continuously be associated with the solutions or the washings which may be necessary for thoroughly exhausting the values from the ore. This is accomplished by constructing a leaching tank, in the form of a long trough, which may be divided by one or more fixed or removable bridges into so many trough sections as are required for the several solutions or washings when

one leaching is not sufficient; or by providing a series of tanks or troughs operatively arranged with respect to each other, employing in connection therewith a conveyer for the ore pulp adapted to continuously feed the pulp with a steady movement through the several solutions in an uninterrupted flow through the apparatus to the point of discharge without any intermediate stoppage or handling of the same whereby the lixiviation of the ore is effected.

For the purpose of rendering the operation continuous, provision is made for a constant drawing off of the charged solution or solutions from the leaching troughs and an inflow of fresh solution thereto. In the case of the first cyanide solution the inflow is preferably at the ore-entrance end of the trough or trough section and the current is with the ore, thus catching the fine float gold carried by the fresh pulp; but in the subsequent troughs or trough sections, and also in the first, if preferred, the inflow of the solution (or washing water) is preferably made at the ore-exit end and the outflow of the solution is at the opposite end where fresh ore or pulp is entering the trough or trough section. Thus, in this latter case, the flow of the solution is opposite to that of the ore. The fresh cyanide solution first acts upon pulp which is largely leached out, and as the solution becomes more and more charged with the gold or precious metals it meets pulp that is progressively richer in the metals, and the conditions are therefore favorable for effecting a complete extraction of the precious metals by the solvent. As a preferred form of conveyer, slowly-moving blades transverse to the trough or tank are used. These blades extend across the tank with just enough room at the sides for clearance, and they reach from above the surface of the solution down to and into the ore pulp on the bottom of the tank with openings or notches in or along the lower part of the blades for the underflow of the solution. These blades divide the trough or tank into a number of communicating divisions and form what may be called "traveling partitions," moving slowly through the trough from end to end thereof. The lower edges of these blades are preferably fashioned with rake teeth, and they open up and rake along the layer of ore pulp on the bottom of the tank and effect a slow and progressive movement of the mass with a constant plowing therethrough and exposure of fresh portions thereof to the action of the solution, while the solution in the tank as the series of blades move forward has to flow back through the notches or openings in the bottom of the traveling blades from each of these divisions formed by the blades, respectively, into the adjacent rear division, and thus there is secured a constant and steady underflow of the solution in close proximity to the agitated pulp. This flow of the solution is in addition to and distinct from the flow due to the constant addition of fresh solvent at one end of the trough and the drawing off of the charged solution at the other end thereof; but it will be seen that the underflow thus effected prevents a mere surface flow of the solution from one end of the trough to the other. On the contrary, as the flow from the respective divisions of the trough is from the bottom and under each traveling partition or blade, the overflow or discharge from the trough at the end is necessarily of the charged portion of the solution. It will be seen that this method of leaching ores places the ore and the solvent under perfect control, which is a very great advantage with respect to the economical leaching of ores. There is an agitation and constant shifting of the pulp in the solution, which very much accelerates the action of the solvent and shortens the time required therefor, and the speed of the conveyer can be regulated so that the pulp will not remain in the tank or tanks any longer than is necessary, and yet long enough for the extraction of all value therefrom. On the other hand, the flow of the solvent through a tank can be gauged so that it will issue from the tank fully charged or charged to the degree most profitable under all the conditions of the case.

576118—February 2, 1897. W. F. Heathman. *Means for extracting gold and silver from sea water.*

In order to extract said metals, the sea water or salt lake water is passed through a filter made of carbon, and the gold and silver held in solution in the sea water or salt lake water are freed from the chemical combinations in which they occur in the water. The chlorides and bromides of gold and silver in solution when passing through the carbon filter are decomposed by the reducing power of the carbon, the liberation of chlorine, and the destruction of the bromine combination, with the result that metallic gold and silver are precipitated in the carbon filter and deposited in the pores and upon the surface of the carbon. And the inventor claims a tank mounted on suitable supports and provided in its side with an inwardly opening valve or gate, said tank having a perforated bottom, and a filtering medium arranged on the bottom and comprising alternating layers of coarse and fine carbon, a layer of wire cloth, and a perforated top covering.

584627—June 15, 1897. J. J. Deeble. *Apparatus for extracting gold from auriferous material.*

This invention has been devised in order to provide a machine for use in the extraction of gold from auriferous material by the aid of chemical solvents, in order to insure the particles of auriferous material being brought into intimate contact with the cyanide or other solvent solution. It includes a vat or pan to receive the auriferous material to be treated, having at or about its center a vertical shaft or spindle with one or more agitators or stirrers attached to its lower end. Motion is imparted to this shaft or spindle by bevel gearing or other convenient mechanical contrivances, and means are provided for reversing the rotation and controlling the speed of the agitators, as well as for raising or lowering the agitator shaft or spindle. These means may consist of a screw-threaded lifting rod with correspondingly threaded bevel wheel in gear with a bevel pinion fitted with a crank handle, whereby it may be rotated in the required direction; or, if preferred, a rack and pinion may be used for the purpose. The inner side of the wall of this vat or pan is provided with a series of projections which produce eddies or swirls in the material under treatment as it is carried round the vat or pan. In order to drain or draw off the gold-bearing solvent from said vat, it is provided with a vertically sliding valve. A waste discharge valve may also be provided in the lower part of the vat or pan for the purpose of enabling the waste material to be sluiced therefrom after the gold has been dissolved and the gold-bearing solution has been drawn off through the valve above referred to.

587408—August 3, 1897. H. L. Sulman. *Method of recovering precious metals from their solutions.*

This invention has for its object the recovery of precious metals from solutions of the same by means of a new and improved apparatus, the apparatus being constructed to effect the deposition or "precipitation" of the precious metal or metals in solution upon a "precipitating" substance or "precipitant" which is in a solid but more or less finely divided state.

The apparatus is designed to recover these metals from solutions of their haloids by means of the employment therein of dense but more or less finely divided carbon, subsulphide of copper, or other suitable precipitant; again, also, for the recovery of the same metals from their cyanide solutions by means of the finely divided zinc product commercially known as "zinc fume," and generally for analogous requirements.

It is necessary that whatever the nature of the precipitant used and the degree of fineness to which it is found desirable to reduce it primarily, it shall be of greater specific gravity than the liquid or solution desired to be precipitated by it, so that the precipitant shall tend to settle from the liquor by gravitation. Further, it is necessary to this invention that the solution or liquor to be precipi-

tated shall percolate upward through the mass of solid finely divided precipitant.

In an apparatus with parallel vertical sides the upward flow of liquor would tend to carry off finely divided particles of precipitant unless special means were taken to prevent this. Filters tend to become clogged and are generally useless for this purpose, so that the inventor retains the particles of the solid precipitant, upon whose surfaces the precious metals are in course of deposition, within the apparatus by inducing subsidence of them. This is effected by continually reducing the upward rate of liquor flow, which is secured by constantly increasing the area of the liquor column as it rises higher in the apparatus.

The apparatus takes the form of a funnel. The liquor enters (under a sufficient pressure or "head") through the bottom orifice. It then meets with and thoroughly mixes with the mass of finely divided precipitant in a condition of suspension in the liquor. The solid, finely divided particles do not sink against the comparatively rapid inflow, or are prevented from doing so to any extent, by means of an automatic valve of ordinary type. By this intimate admixture of liquor with precipitant the deposition of the precious metals in solution in the former is effected upon the minute surfaces of the latter. It now only remains to remove the depleted liquor from the particles of the solid precipitant containing the gold, silver, etc. As the liquor continues its upward flow by virtue of the continually diverging sides of the apparatus the area of the liquor column becomes greater and greater. The rate of the vertical upflow is thereby correspondingly reduced. This continues until a point is reached at which the upflow is vertically so slow that the finest particles are able to settle or subside against it. At any point, therefore, above this limit or "zone" the absolutely clear liquid may be drawn off from the apparatus free from suspended particles and depleted of its precious-metal contents.

If the precipitation of the precious metals be deemed to be incomplete in one apparatus, owing to the richness of the original liquor or to other causes, the outflow may be caused to pass into a second similarly arranged apparatus or through two or more such apparatus placed in series; but in general one apparatus can be made to secure practically perfect removal of the precious metals dissolved in a given liquor by the use of a suitable precipitant. If a series of two or more of such apparatus be employed, the first of the series may be used to enrich quantities of precipitant which have only been partially used up to their fullest capacity of precipitating the precious metals, while the succeeding members of the series are supplied with the necessary amounts of less rich or quite fresh precipitant in order to remove any remaining traces of gold, silver, etc., which may escape unprecipitated in the outflow from the first apparatus. The poorer precipitates in these last apparatus are in course of time removed through the bottom of the apparatus and transferred to the first one of the series, there to be enriched to their full capacity, while their place is taken by fresh quantities of poorer or quite unused precipitating agent, and so on.

When the precipitate is deemed to be sufficiently rich, it is removed from the apparatus by a "three-way cock" at the bottom thereof, or by other suitable arrangement, and the precious metal it contains finally recovered by any suitable method, such as in the case of the employment of a carbon precipitant by burning, or in the case of the use of a zinc precipitant by smelting.

The apparatus is also supplied with a small central funnel for the introduction of fresh quantities of precipitant from time to time to the point of maximum precipitating action in the apparatus, i. e., near the inflow. By providing this funnel with a bell-shaped or inverted-funnel termination a sort of "chamber" is produced in the lower part of the apparatus having an annular space for the passage of liquors between the rim of the smaller funnel and the sides of the large one. This chamber is of considerable aid in promoting the action of the precipitant by keeping the bulk of it constantly near the liquor inflow and securing perfect admixture by means of the vortex currents, etc., it induces. It is further desirable to break up the rapid rush of inflowing liquors at their point of entry into the apparatus, and to secure their subdivision and intimate admixture with the precipitant as early as possible. This is effected by capping the end of the inlet pipe with a small perforated cone or "distributer." The perforations may be from one-fourth to one-tenth the diameter of the inlet pipe, but their total area must be larger than that of the sectional area of the pipe. The holes may be bored in a direction perpendicular to the cap cone or they may be made "tangential," i. e., bored at a tangent to the internal circumference of the cone, thus securing a rotary initial flow of the inflowing liquors instead of a series of straight streams. In the majority of cases, however, perpendicular bore holes answer equally well.

The clear precipitated liquor may be drawn off at any point above the limit of subsidence either by a pipe, or, preferably, by allowing it to flow equally over the rim circumference of the apparatus. The latter method secures the quieter and more uniform outflow and does not disturb the top layers of liquor undergoing final subsidence by establishing a quick current in one particular direction.

If desired, the rim may be encircled with a filter screen of lawn, calico, or other filtering or straining medium, so as to retain within the apparatus any particles of precipitant which may be floated or "buoyed up" by bubbles of air or other gas.

The clear liquors passing over the rim and through the precautionary filter or strainer fall into and are collected by a circular trough or "launder," attached to the apparatus below the rim, whence they are conveyed away by a pipe. As before stated, this may lead into a storage vat or into another similar apparatus, or, if deposition of the floating particles is not absolutely complete, into any suitable type of apparatus—such, for example, as the slat-partitioned tank used for freeing softened water from traces of deposit—where subsidence is finally rendered absolute. In most cases where the traces of precipitant have escaped, I have secured perfect final subsidence by allowing the liquors to flow through a shallow plain tank of from four to six times the area of the top of the precipitating apparatus before passing them direct to the storage liquor vats.

Such an apparatus as is described is termed a "precipitating cone." It may be constructed of any suitable material, such as wood, stoneware, galvanized iron, etc., according to the nature of the liquor or precipitant it is designed to treat. Its action, until the charge of precipitant it contains is exhausted and requires renewal, is perfectly automatic and continuous. Its capacity, its height, the angle of its sides, the ratio diameter of inflow pipe to top area of cone will naturally vary with the volume of liquor to be dealt with, the rate and head of liquor inflow, the relation of the specific gravity of the liquor to that of the finely divided precipitant, the actual coarseness or fineness of the particles of the latter, and so on. These data may be calculated or decided by preliminary experiment in any particular case. As an example, however, of the application of this invention to the recovery of gold bullion from cyanide solutions, the following dimensions of the apparatus are cited: For a flow of from 600 to 800 gallons per hour a depth of 5 feet, with a top diameter of 5 feet, is amply sufficient. The diameter of the inlet pipe is from $1\frac{1}{4}$ to $1\frac{3}{4}$ inches, according to the head of the inlet liquor, while the perforations of the cap cone or distributer are three-sixteenths of 1 inch in diameter. The charge of zinc fume in such an apparatus varies from 5 to 30 pounds, according to requirements.

587874—August 10, 1897. E. D. Sloan. *Barrel filter.*

The object of this improvement is to provide a suitable filter barrel, with a durable and highly effective filter, at comparatively low cost. With a view to securing the desired ends the usual

trunnioned iron barrel is lined with lead. The framing of the filter bed is composed wholly of suitable wood capable of fairly resisting the action of chlorine and acids, and which may be filled with suitable matter to enable it to better resist the destructive action of the corrosive solutions. The filtering medium is composed of material which resists the solutions, is well protected against undue abrasion due to the action of the solid matter during the rotation of the barrel, and it has its filtering area supported to enable it to safely bear the overlying contents of the barrel by an underlying floor of such metal as will practically resist the action of chlorine and sulphuric acid—as, for instance, a lead floor—and the latter is freely perforated to admit of the prompt discharge of the filtered liquid. The filtering surfaces are flat, and hence the body of any woven filtering medium is maintained in a condition more favorable to the passage of the liquid than would be the case if it occupied a curved line and said surfaces were concave in conformity with the interior contour of the barrel. The framing of the filter bed involves inexpensive straight work as distinguished from the curved or segmental work in framing, which is made to conform to the interior of the barrel as heretofore, and the filter framing is constructed in parts which are so interlocked as to secure rigidity, but which may be readily applied to or removed from the barrel by way of the usual manhole and without deranging the lead lining or the means by which the lining is clamped to the barrel.

597372—January 11, 1898. P. J. Donohue and J. F. Corker. *Precipitating safe.*

The combination with a closed vessel or standpipe provided with a normally closed outlet at its bottom for the precipitate and having a body or column of zinc filings or like material in its upper part, adapted as corroded to fall into the lower part, of means for supplying, under pressure, the solution containing the precious metal to the lower end of the said body or column of filings or like material, to cause the corrosion or oxidation thereof, whereby such corroded or oxidized portions will gradually precipitate to the bottom of the vessel or standpipe and the fresher portions of the filings or like material be exposed to the ascending solution.

606810—July 5, 1898. J. W. Pack. *Recovery of gold from waste solutions of chlorination works.*

A means for recovering gold from waste solutions of chlorination works, consisting of a tank having an inlet passage at the lower portion and an outlet passage at the upper portion and having metallic aluminum contained therein, and intermediate between the inlet and outlet passages of the tank, and a filter fixed within the tank between the metal and the outlet passage and having its lower side coated with a substance which will arrest the fine precipitated gold and prevent it from passing off with the liquid.

608554—August 2, 1898. R. Moodie. *Washing or leaching apparatus.*

In an apparatus for washing or leaching, a series of cells, one of which is a dry cell and the others of which contain washing or leaching liquid, means for introducing the material to be washed into the dry cell, an oscillating shaft extending longitudinally of the series of cells, means operated by said shaft to transfer the material from the dry cell to the washing cell next in series, arms attached to the oscillating shaft and extending one into each washing cell, and scoops on said arms.

608945—August 9, 1898. H. B. Williams. *Lixiviation apparatus.*

In a lixiviation apparatus, the combination of a vertical series of annular tanks arranged one above another and each provided with an exit through which ore or other substances may be discharged into the tank beneath, each tank bottom being provided with an ascending incline leading to one side of the tank exit and having a descending incline on the other side, means for feeding ore into the topmost tank, pipes for conveying leaching solution into the several tanks separately, the feed of the ore to be continuous and the feed of the solution to be continuous or intermittent, filters located in the several annular tanks, and automatic scraping and stirring mechanism to cause the ore and solution to be moved around each annular tank and over the filter therein.

610596—September 13, 1898. R. Aymer and D. J. Nevill. *Filter frame.*

In a filter barrel, the combination of a rubber grating having a corrugated surface in contact with the curved inner lining and periphery of said filter barrel adapted to allow the filtering solutions to run along and down the lining of said barrel, a perforated bedplate of glass or porcelain curved concentric with the inner periphery of said barrel and resting on said rubber grating, a filtering medium on said glass bedplate, a curved glass grating resting on said filtering medium, two oppositely disposed cleats secured lengthwise of said barrel to its inner periphery adjacent to the ends of said curved glass bedplate and grating, and wedge keys between said ends and said cleats adapted to key said members against the barrel.

611515—September 27, 1898. J. P. Schuch, Jr. *Means for extracting precious metals.*

In a metallurgical apparatus for treating ore by a cyanide solution, a tiltable tank comprising a suitable support, a tank body having a discharge gate at its rear end and pivoted to the support at a point between its center and the front end, a drain device in the bottom of the tank for drawing off the cyanide solution, holding springs mounted on the support and engaging with the tank body at points between its discharge end and the pivotal connection thereof with the support, and means for retracting the holding springs from engagement with the tank body.

611935—October 4, 1898. J. Poole. *Process of and apparatus for treating ore tailings.*

For the continuous treatment of pulps, slimes, tailings, and the like with cyanide and similar solvent solutions and in combination, a series of shallow tray-like baths, a rake in each bath of the series, means for reciprocating the rakes, an overflow chute at the end of the series, settling tanks to receive the overflow from the chutes, means for separately discharging the solid and liquid contents of the tanks, conveyers adapted to raise the solid contents from one tank after discharge, a launder in which such contents are received and in which they may be further treated with a solvent solution or wash, and a further settling tank for receiving the discharge from the launder.

615968—December 13, 1898. T. Craney. *Apparatus for treating ores, etc.*

In an apparatus for treating ore, the combination of a tank adapted to contain a body of the ore to be treated, devices for feeding ore into the top of said tank and discharging it from the bottom thereof at a point above the tank in a continuous manner, a solvent supply reservoir, a receiver connections between the tank and said supply reservoir, and receiver for producing a continuous flow of the solvent through the tank in a direction opposite to that of the movement of the ore, an endless-chain carrier in proximity to the tank and having draining buckets adapted to receive the ore discharged from the tank, means for discharging a liquid upon the drainage buckets, and means for collecting the drainage from the buckets and returning it to the aforesaid supply reservoir.

617029—January 3, 1899. W. A. Köneman and W. H. Hartley. *Apparatus for separating liquids from solids.*

The method of abstracting liquid from finely pulverized ore, ore slimes, or other solids impervious to percolation with which the liquid is mixed, which consists in subjecting the mixture to gaseous pressure applied above the same, and simultaneously to the action of a partial vacuum applied below the same, removing a portion of the liquid by filtration below the body during compaction of the solids,

and collecting and abstracting by pressure the remaining liquid above the compacted solids.

617497—January 10, 1899. P. ARGALL. *Cyanide filter tank.*

In a cyanide filter tank, a vertical metallic side or wall, a horizontal bottom secured thereto, having a central opening, a packing ring secured to the inside of said wall, near the bottom, with a spacing, a system of level joists converging from the perimeter toward the center, upon said horizontal bottom, a plastic filling between said joists sloping downward from the packing ring regularly toward the central opening, a level floor with interstices laid upon said joists, permeable filtering material upon said floor, and a covering of textile fabric, the outer margin of which is packed into the crevice between the packing ring and the vertical wall.

618622—January 31, 1899. P. SOMERVILLE. *Apparatus for extracting metals.*

An apparatus for extracting metals, consisting of parallel barrels having annular disks closing one end with central inlet openings for the material, a framework and roller support for said barrels, means whereby the barrels are rotated in opposite directions, spiral flanges fixed to the interior of the barrels for advancing the material therethrough, devices for feeding material and fluid matter to the uppermost barrel, means for separating the coarse from the fine material and delivering them separately, and means for transferring material from the discharge end of one barrel into the inlet end of the barrel below.

619211—February 7, 1899. A. M. NICHOLAS. *Filtering apparatus for separating gold and silver bearing solutions.*

This invention has been devised for the purpose of providing means whereby solids or insoluble material may be separated from liquids carrying same in suspension, but more particularly for the purpose of providing means whereby the separation of gold and silver bearing solutions from tailings, slimes, pug, or pulverized ore may be carried on continuously and in such a way that a clean or partially clean filter cloth will be continuously brought into operation without necessitating stoppages for recharging, as required with the appliances at present in use.

The essential feature of the invention consists in the use of a rotating wheel, disk, or table formed with a series of air-tight compartments covered with cloth or other filtering material supported upon a metal screen or perforated plate and adapted to be automatically placed in communication with a vacuum pump in turn for a sufficient time to enable the liquid to be drawn through the filtering material, leaving the solid constituents upon the filtering surface, whence they can subsequently be removed by brushes, jets of water, scrapers, or similar contrivances, provision being made for automatically allowing air to enter into the various compartments at the desired period of the operation to facilitate the removal of the solids from the outer surface of the filtering material.

620660—March 7, 1899. J. LUCE. *Apparatus for treating ores by lixiviation.*

In a tank for the treatment of ores, a lining composed of asbestos applied to the inner side of the tank, the notched or recessed boards applied inside of the asbestos, and the steam pipes placed in the notches in the boards, combined with two thicknesses of grooved perforated boards, and the layers of cloth between the boards.

623465—April 18, 1899. G. S. DUNCAN. *Apparatus for separating gold and silver bearing solutions from ores or slimes.*

Hitherto upward percolation has been used for the displacement of the various gold and silver bearing solutions in the treatment under the cyanide or other similar processes of tailings or free leaching ores which are not in the form of slimes. With this upward percolation false bottoms for the vats with webbing upon them have been used and the solutions have been introduced underneath these false bottoms, which have acted as distributers therefor and allowed them to pass evenly up through the free leaching ore, displacing the gold and silver bearing solution contained therein. This false bottom and webbing are adapted for use with free leaching ores only and can not be employed for displacing solutions used in treating very finely crushed ores or slimes which do not leach freely.

The present invention has been devised in order that the various solutions may be displaced, as above described, from finely crushed ore or slimes, without the aid of any false bottom and filtering-webbing. And the inventor claims, in an apparatus for separating solutions of the precious metals from residual ores and slimes, the combination with a leaching and displacement tank or vat and with a vat to hold said solutions, the latter being placed at a higher level than the former, of a series of pipes to convey said solutions from the higher vat, the discharge ends of said pipes entering the leaching vat, a series of hoods having slightly arched portions which overlie the said discharge ends, and stirring arms radiating from a central shaft in said vat, the arched portions of the hoods being arranged in radial lines, or at right angles to the movement of currents set up by the stirring arms.

623772—April 25, 1899. A. F. DUEY. *Apparatus for leaching ores.*

A device for treating pulverized ores, comprising a leaching tank, an air compressor, a tank for storing the leaching liquid, a perforated pipe in the bottom of the leaching tank, connections from the air compressor and liquid storing tank to the perforated pipe, a perforated drainage pipe in the bottom of the tank, and a layer of filtering material about said pipe.

624533—May 9, 1899. C. H. PEAD. *Slime filter.*

The apparatus consists of a tank fitted with a hood of conical or any other convenient form. The sides of the tank project above the point of attachment of the hood, so as to form an annular space to act as a receptacle forming a launder for discharge of the clear liquid. In the center of the hood is an opening, around which is riveted or bolted a frame or seating arranged to carry a filter composed of one or more layers of filter cloth or any other well-known filtering medium. The filter is kept in place by means of a protective gird or clamp of suitable form and strength to resist the effective pressure from the interior of the tank. A number of small distribution pipes set at such an angle as to cause the slimes to impinge on the under surface of the filter are connected to the seating of the latter, through which they pass. They are connected to a main distributer, which in turn is connected with the delivery pipe or column of the slime pump. One or more taper shaped plugs or cores constructed of light steel tubes, their number varying according to the size of the tank, pass through the hood and extend to the bottom of the tank. They taper from about 18 inches at the top to 15 inches at the bottom. They are fitted at their upper ends with a flange, to which is attached a shackle. Their lower ends are closed by means of a dished bottom riveted in place and having a strong bolt or stud fitted to its center. Each plug or core rests on a seating fitted to the outside of the hood and through which the plug or core passes. The seating is attached thereto by means of its flange.

In the bottom of the tank and directly under the aperture in the hood through which the plug or core passes is a discharge door of the ordinary manhole or other convenient type. The end of each plug or core passes easily into the discharge opening, and the discharge door is drawn up onto its seating or joint by means of the bolt or stud on bottom of the plug or core and by its nut. The plugs or cores when in place and holding up the manhole doors afford an effectual means of resistance against internal pressure.

A special pipe is arranged and fitted to the upper portion of the tank to drain the space forming a launder between the top of the tank and the upper surface of the hood and to conduct the liquid portion which has passed through the filter to the precipitation boxes or to waste.

624633—May 9, 1899. F. A. Edwardes. *Apparatus for use in treating metallic ores.*

In apparatus for use in the treatment of metallic ores, the combination with an annular vat having a stirrer moving therein and skimmers attached to and moving with the said stirrer, of means for tipping the said vat for discharging the contents.

624957—May 16, 1899. L. H. Mitchell. *Tank bottom discharge door.*

A discharge apparatus for tanks provided with a hollow upper portion, a base having integral bearing zones connected thereto at one end thereof, a casting having an upper annular supporting rim and adapted to receive said bearing zones, a ring surrounding said casting, devices connecting said rim and ring to secure the casting in position, and means supported by said casting to unseat said base.

624958—May 16, 1899. L. H. Mitchell. *Tank bottom discharge door.*

A discharge apparatus for tanks consisting of a casting secured in the bottom of the tank, a ring below the tank around the casting, and means for securing the rim and ring in position, a funnel above the casting, a base connected with the lower end of the funnel and provided with an annular offset or shoulder, a packing ring within the offset, and adapted to rest upon the rim of the casting, a plate or bar bearing against the rim of the casting, a nut carrying screw in the plate or bar adapted to engage the base and draw the same within the casting, a brace or clamp connected to the plate or bar above the nut on the screw, and means for rotating the screw.

639540—December 19, 1899. W. Duncan. *Means for mixing and aerating sands or tailings while under treatment by solvents.*

Numerous attempts have from time to time been made to secure the thorough mixing of sands and tailings, including slimes, with the solvent while under treatment and also to prevent that close packing which prevents the percolation of the solvent and wash liquors. For this purpose vertical vessels with vertical agitators, revolving barrels, and air, steam, and water jets have been used, but these means have not been as efficient as they might be.

This invention relates to improved mechanical means for mixing and aerating "sands" or "tailings," by which terms are included slimes, sludges, and concentrates, while under the action of solvents, whereby time is saved and a better extraction is obtained; and it consists of a semicircular vat provided with a revoluble agitator composed of arms arranged helically on a shaft running the length of the vat. At one end of the vat is placed the fast and loose pulleys and gear for slowing and rotating the agitator, while at the opposite end a series of taps are provided connected to the vat at various heights and to pipes, so that the liquor can be drawn off at any desired point and either run direct to the sump or through a filter to the sump.

641419—January 16, 1900. H. C. Wheeler. *Agitator.*

In an agitator, the combination of the vat, the track provided with the cog rack, the carrier provided with the pinion meshing with the cog rack, the first driving shaft provided with the driving pinion, the driven cogwheel meshing with the driving pinion, the gear wheels connecting the driven cogwheel with the pinion meshing with the cog rack, the agitator frame journaled or pivoted to the carrier frame, the second driving shaft journaled in the agitator frame, the agitators journaled in the agitator frame and adapted to be operated by the second driving shaft, intermediate gearing connecting the second driving shaft with the driven cogwheel, one of such gears being journaled with its axis in line with the axis of the pivotal support of the agitator frame, and means for rotating the first driving shaft.

647358—April 10, 1900. D. W. Balch. *Leaching tank.*

A tank having a bottom, a leaching false bottom above the same, and vertical filtering partitions arranged in pairs within the tank, whereby spaces are left between pairs of partitions, and other spaces are left between members of such pairs, said spaces last named all communicating with the chamber between the bottom and false bottom.

647678—April 17, 1900. C. W. Merrill. *Means for charging leaching vats.*

This invention relates to a method of charging ore or tailings to a leaching vat, which process is a step in the treatment of said ore or tailings preliminary to the application of the solvent solution in cyanide, hyposulphite, or other hydrometallurgical processes.

It consists, essentially, in conveying the tailings or ore by any well-known adaptable mechanical means to a point above the center of the vat to be charged and delivering the material there to a hopper, which feeds a revolving chute inclined at an angle greater than the natural slope of the material to be handled, and with openings adjustable both as to size and position, through which the material to be treated falls gently into the vat and distributes evenly, thus giving a charge of minimum density and maximum homogeneity, the conditions most favorable to successful leaching and dissolution of the precious metals.

The ordinary method of charging leaching vats is from cars running on a superimposed track. By this means the momentum of the carload of tailings or ore dropping through five or more feet to the bottom of the vat is such as to produce considerable packing, and, moreover, an uneven packing or density. For instance, in dumping from an end discharge car the resultant mass of ore or tailings will take the form of a cone in the vat and the maximum density will be in the center of the approximate circle forming the base of the cone and will decrease along the radii toward the circumference of this circle. Furthermore, the variation in fineness of the different carloads is not equalized, and a vat charge of ore or tailings results, which is heterogeneous, both as regards density and as regards fine and coarse material. Now, first, the charge of ore or tailings in a vat should be of the least density possible to obtain, because experience has demonstrated that the greater the permeability, and consequently the greater the amount of lixiviant possible to percolate through the charge, the greater the extraction of the precious metals in a given time, or, from another standpoint, the greater the permeability the less the economic period for leaching, and hence the less the cost for plant and subsequent operation; second, the charge should be as nearly homogeneous as possible as regards both density and size of material, because in leaching ores it is necessary to follow solution with wash water to replace and prevent the loss of the former or to follow one lixiviant with another of different strength or containing a different solvent, and in doing this to maintain the surface of demarcation between the one and the other as nearly a horizontal plane as possible in order to minimize the mixing of effluent solutions. The above conditions of minimum density and maximum homogeneity are produced by means of a revolving inclined wide chute with small openings in the bottom, adjustable as to size and position transverse to the direction of the stream of ore or tailings. By means of this method a number of very small streams of ore or tailings fall gently into the vat as the chute revolves, and by increasing the speed of revolution a carload of fine or coarse material can be spread over the whole area of the vat, thus giving the smallest possible dimension parallel with the course of the lixiviant.

653631—July 10, 1900. J. C. Wallace. *Filter barrel or tank.*

In a filter barrel or tank, a filtering device consisting of a series of curved metal plates, perforated, fastened to the inside wall or walls of said barrel or tank; a filter cloth upon the upper surface of said plates, secured thereon by a series of imposed metal bars and filling strips secured in position by bolts or other fastening devices to the wall or walls of said barrel or tank.

653684—July 17, 1900. F. H. Long. *Metallurgical filter.*

The combination with a closed vessel having a filter septum and a regulated outlet port for the filtrate beyond such septum, of the wash water pipe connected in hydrostatic column with said vessel

and the external centrifugal pump joined at its separate sides in closed union with the opposite ends of the vessel, the journal box for said pump axle being furnished with a water column pipe to counterbalance the hydrostatic pressure at the vessel.

654315—July 24, 1900. T. E. Leece. *Apparatus for working ores of valuable metals.*

This invention relates to an apparatus which is designed for working the ores of valuable metals, and is especially useful for separating slimes from solutions in which they may occur, and also for separating heavier and lighter parts under any condition in which they may be found associated.

It consists, essentially, of a tank and an endless traveling belt with directing rollers, by which one portion of the belt is caused to travel through the tank in close proximity with the bottom, and the other part is guided back exterior to the tank by similar rollers. It also comprises a means for straining or separating the liquid from the heavier portions.

660498—October 23, 1900. J. A. Fleming. *Apparatus for leaching ores.*

In an ore leaching apparatus the combination with the leaching tank having a pulp discharge, of the conical perforated filtering hopper therein having the discharge for the pulp, means by which to maintain air pressure below the diaphragm, whereby to control the flow of solution through it, means for the introduction and withdrawal of chemicals to and from the body of the tank above the filtering diaphragm, and devices for controlling the discharge of the pulp from the tank.

660499—October 23, 1900. J. A. Fleming. *Apparatus for leaching ores.*

An ore leaching apparatus, consisting of the leaching tank, having a filtering hopper, a solution discharge below said hopper, and a pulp discharge also below said hopper and independent of the solution discharge, a washing tank below the leaching tank and in position to receive the pulp from the discharge thereof, and means for controlling the passage of the pulp from the leaching to the washing tank.

664059—December 18, 1900. J. P. Schuch, Jr. *Ore mixing machine.*

Heretofore, in treating gold bearing ores by the common cyanide process, the ore is first crushed, dried, and rolled to a proper degree of fineness, and that which requires roasting is then conveyed to the roasters, while the oxidized ore which does not require roasting is conveyed to the bin or receptacle therefor. After the portions of the ore to be roasted have passed through this step of the process the same is conveyed to the cooling room before being deposited in the bin or receptacle referred to which contains the ore requiring no roasting. All of the ore is then removed by manual labor into the ordinary stationary cyaniding tanks, and after these tanks are filled with the ore the cyanide solution is introduced therein. In this process the filled cyanide tanks, with the solution and ore therein, are permitted to remain filled and unmolested for a sufficient length of time for the solution to act on the ore, after which the gold bearing solution is drawn off and allowed to flow to the precipitation room, while the tailings in the tank are then washed with water and shoveled out or sluiced out when this is possible. In this process, which is the one usually followed out in extracting gold and silver from their ores by the use of cyanogen containing solvents, the percentage extracted rarely exceeds 80 per cent of the ore value, and it is the purpose of the present invention to provide means whereby a larger per cent of the value of the ores may be saved.

To this end the invention contemplates an improved mixing machine which provides for a thorough aeration of the ore and solution, while at the same time providing for a mixing of various grades of ore with the cyanide solution, so as to make one even grade out of ores of various values. And the inventor claims, in an ore mixing machine, an open tank provided at the bottom with a solution drain, a perforated false bottom arranged within the tank above the main bottom and supporting filtering material, an ore discharge pipe communicating with the interior of the tank immediately above the plane of the false bottom, a revoluble agitator depending within the tank into close proximity with reference to the false bottom, and a plurality of air jets arranged to communicate with the tank in a plane intermediate the said false bottom and the lower end of the agitator thereabove.

664196—December 18, 1900. J. C. Wallace. *Filter bed.*

In a filter barrel, a filter bed consisting of a series of metal plates having drain slots or perforations therethrough, a series of perforated tiles arranged as a filtering medium upon and supported by said metal plates, a series of metal binding strips imposed upon or against said tiles; together with suitable means for fastening or confining the same together and to the inner wall of a filter barrel or tank.

671028—April 2, 1901. J. R. Phillips. *Pulp agitator.*

This invention consists of an inclined or funnel shaped tank or containing vessel into which the pulp is placed with water, cyanide solution, or other equivalent liquid, a circulating or suction and force pump by which the surface liquid may be drawn from the tank, and a pipe extending centrally down to near the bottom of the cone, with a discharge nozzle through which the liquid is delivered with force, so as to flow upward along the sides of the funnel and through the material, whereby the latter is loosened, agitated, and prevented from packing. In conjunction with this may be used a canvas or equivalent filter lining for the funnel, with means for providing a space intermediate between it and the sides of the funnel for the filtering through of water, and a means for conducting such filtered water away from the apparatus.

680154—August 6, 1901. A. D. Jansen. *Discharge door for cyanide tanks.*

In cyanide treatment the sands are subjected to the action of cyanide solution, which solution after the proper length of time has elapsed is drawn off through a filter composed of matting or some similar material situated at the bottom of the tank. This matting or filtering material does not rest directly on the bottom of the tank, but is supported by a grating or perforated false bottom in order to allow a free passage for the solution which has filtered through. That portion of the tank, therefore, which is situated over the discharge door has no grating or filtering material, and consequently a more or less vertical column of sand is left in the tank, which still contains cyanide solution with gold in solution, the result being that this portion is imperfectly treated.

The object of this invention is to provide a door so constructed that a piece of matting or filtering material may be placed upon it in order that the filtration of the solution shall be just as complete over the discharge door as in the rest of the tank.

This invention furthermore relates to an improved construction whereby the door is rendered much more easily closed and also to a system of packing the same by which the joint between the door and the bottom of the tank is rendered tight.

683412—September 24, 1901. A. J. Perry. *Ore separator.*

The object of this invention is to introduce a mixture of steam and air in the pulp, whereby the precious metal receives a quick chemical action, with the result that considerable time is gained over the method heretofore employed. And the inventor claims, in a leaching apparatus, the combination of a receptacle for holding pulverized ore, an agitator mounted in said receptacle and having a series of radial horizontal pipes each provided with a series of perforations at one side thereof, a series of scrapers or blades mounted on said agitator, a pipe adapted to supply to said agitator a mixture of steam and air from a proper source, and means adapted to rotate said agitator whereby the discharge of steam and air through the perforations of said pipes is directed toward the rear while the said scrapers or blades are moving in the opposite direction.

684654—October 15, 1901. C. Voelker. *Ore filter.*

The extraction of valuable metals from ores through the lixiviation processes, such as the cyanide and others, although allowing the advantageous working of low-grade ores, still has one fault, that more or less metal remains in the tailings, and thus losses occur caused by the slimy particles contained in the pulverized ores generated from clay, talc, and other minerals which clog up the meshes of the filtering cloth, and thus prevent the solution from going through freely. In such apparatus the ore is introduced and the solution added, and where it happens that the ore lies in different grades of value inside the tank, the solution can not dissolve the metalliferous particles in an even manner, and at the same time where it enters first it will affect the pulp more thoroughly, and as it goes down to the bottom will take the slimes forming with it, depositing them around the aperture through which the solution is drawn off, and even several after leachings will not remove them. To overcome these drawbacks it is necessary to construct a mechanical apparatus which shall possess the condition of letting the soluble liquids needed to dissolve the metals go through the pulp in a space of time to be governed by the operator. Some ores are liable to contain chemical substances retarding the effectiveness of the soluble agent used, and where it is of great import to remove them as quickly as possible to keep them from going into chemical action with the solution used.

The object of this invention, therefore, is to combine the above-mentioned conditions, and the apparatus can be used, in addition to other milling plants, to receive the tailings direct from the mill. The filtrate can be examined in regard to the valuable mineral matter which may exist, giving the metallurgist the means of saving the valuable salts of mercury, copper, silver, gold, and the like which may form through the chemical or electrical action in the amalgamators where such are used and where the extravagant use of copper sulphate, mercury, and salt is in most cases the cause of the solubility of gold.

The inventor claims: An ore filter, comprising a funnel shaped tank, a basket or filter holder removably arranged in said tank and fitting closely against its inner wall, a filtering textile stretched over the inner surface of said basket, a top or hood for the tank, a shaft extended downward in the tank, and a screw mounted on said shaft and spaced at its inner edge therefrom, the said screw having the end of its upper turn turned downward.

687920—December 3, 1901. A. D. Jansen. *Apparatus for charging or discharging cyanide vats, etc.*

In combination, the pair of tanks situated one above the other, stirring mechanism for said upper tank, having a hollow supporting or operating mechanism, and stirring mechanism in said lower tank, having its operating mechanism in line with the hollow mechanism of the upper tank, and means for raising said operating mechanism of the lower tank into said hollow mechanism of the upper tank.

688085—December 3, 1901. A. G. Goldsobel, W. Muttermilch, and C. Jablczynski. *Apparatus for the recovery of precious metals from photographic residuum.*

The combination with a vessel having a loose lid, a spout or outlet for the outflow of liquid and a conical bottom and with a precipitating material contained in said vessel, of a tube having a funnel shaped end reaching within said vessel, and of a second tube provided with a cock connecting the aforesaid precipitating vessel and funnel shaped tube with a second vessel or receiver.

689799—December 24, 1901. R. L. Graves. *Ore leaching apparatus.*

The apparatus for use in extracting ores, consisting of a plurality of tanks, a pump, a discharge pipe leading from said pump and having a plurality of branches leading to the several tanks and provided each with a discharge pipe which may be turned axially or swung vertically, valves controlling the several branches, and a flexible supply or suction pipe leading to the pump and arranged to be shifted from tank to tank, levers connected with the several discharge pipes whereby they may be turned axially, and means connected with the lower ends of the discharge pipes whereby they may be swung vertically.

690375—December 31, 1901. G. Rubsch, Jr. *Agitating machine for cyaniding.*

An agitating machine for the treatment of gold and silver ore by the cyanide process, comprising an agitating tank, having a conical bottom; a heating chamber surrounding the conical bottom of the agitating tank; means to heat said chamber; a rotary pump, centrally disposed in the agitating tank, adapted to take the solution from the bottom of the tank and discharge it above the top thereof; a rotary deflector, adapted to distribute the solution over a stationary deflector; and a stationary deflector affixed to the casing of the pump, adapted to deflect the solution to near the edge of the agitating tank.

691706—January 21, 1902. F. H. Long. *Metallurgical filter.*

The combination of a vessel having a conical filter-septum and an outlet-port for the filtrate beyond such septum, of means for establishing an end-to-end circulation of the vessel contents above said septum, a conical spreader and an oppositely facing conical baffle plate having a projecting spiral flange successively interposed between the ends of the vessel and arranged adjacent to said conical filter-septum to intimately direct such circulation over the surface thereof.

697178—April 8, 1902. E. L. Sharpneck. *Apparatus for the treatment of ores.*

As a means for facilitating the dissolving of the values in ores, the combination of a leaching tank, a conduit leading from and discharging directly into the tank, and means in the conduit connected with a heating medium supply for agitating, circulating, and heating the liquid contents of the tank.

698016—April 22, 1902. J. J. Hervey. *Cyanide tank.*

Cyanide tank having a tapering bottom and a central cone arranged in connection with the bottom, an annular lining arranged in the tank and open at its lower end, a filtering screen connecting the lower end of the lining and the central cone, the air and water pipes, the charging and discharging pipes, and the forcing means connected with said pipes.

699211—May 6, 1902. De W. C. Mosher. *Barrel filter.*

The combination with the lead lining of a filter barrel, of filter sections or plates having projections on their outer sides and perforations through the plates between the projections, and having bent ends, whereby the plates may be united to the lining by burning.

699212—May 6, 1902. De W. C. Mosher. *Barrel filter.*

The combination with the lining of a filter barrel, of perforated filter sections, and means for supporting said sections and securing them to the lining, said sections having their adjacent ends so constructed and arranged to form a longitudinal channel.

701239—May 27, 1902. F. D. Wood. *Means for working ores by the cyanide process.*

An apparatus for treating ores consisting in combination of a plurality of aligned containing tanks, a transversely concaved endless belt passing through and returning beneath each of said tanks, and upon which the ore is carried, each of said belts discharging its load upon the belt of the next succeeding tank, means for driving said belts in unison, means by which said belts are kept transversely distended and rollers disposed at intervals in said troughs and over which the belts pass, whereby the latter are given an undulatory movement.

702064—June 10, 1902. F. H. Long. *Metallurgical filter.*

In metallurgic filters, the combination with the closed perforated tank having an internal fabric septum with stretcher frame

therefor to rest against the tank walls of the feed pipe leading into the tank bottom and the separate wash water pressure tube united to said feed pipe between the inlet and outlet valves thereof.

702490—June 17, 1902. R. Seeman. *Apparatus for treating copper ores.*

A plant for the treatment of ores, comprising a safety vessel, a mixer revolubly mounted, a settler revolubly mounted at a lower level than the mixer, and a still revolubly mounted at a lower level than the settler, and pipes connecting the several vessels together, the portions of the several vessels and pipes with which the ammoniacal solution of copper comes in contact being of material indestructible by such solution.

705589—July 29, 1902. A. James. *Apparatus for precipitating gold and silver from their solutions.*

In the precipitation of gold and silver from cyanide and other solutions zinc is usually employed as a precipitant, and the use of iron vessels containing the solutions has been found objectionable, because the iron being electro-negative to zinc a galvanic action is set up between the vessel and the zinc, which causes the precious metal to be deposited upon the vessel instead of upon the precipitant. Owing to this difficulty the general practice has been to use vessels constructed of wood or earthenware, which are inconvenient and do not facilitate the cleaning-up operation.

The object of this invention is to avoid these objections.

To this end the invention consists in a metallurgical filter for separating precious metal from a solution containing it, consisting of a metallic vessel and a zinc sponge disposed therein, said vessel having an inner coating of enamel, whereby galvanic action between the metallic vessel and the zinc is prevented and deposit of precious metal on the vessel avoided.

705726—July 29, 1902. J. C. Wallace. *Filter bed.*

In a filter bed, the combination of a corrugated filter sheet or blanket having numerous perforations through the lower arcs of said corrugations; a series of transverse supporting bars formed to fit under and receive the corrugated contour of said filter sheet; a series of superimposed binding strips or bars with transverse corrugations and slotted ends; two longitudinal side binding strips or bars, and bolts adapted to holding the several members together and in place within a filter barrel or tank.

706334—August 5, 1902. G. Moore. *Apparatus for leaching ores, etc.*

In dissolving the soluble portions of ores, furnace products, and other like materials it has always been difficult in one operation to dissolve the final traces of the soluble portions and at the same time completely utilize the dissolving power of the acid alkali. The weakening of the acid or alkali by its dissolving action makes its action less energetic toward the finish of the operation at the very time when the more difficult soluble particles needing the most energetic dissolving action are acted upon. This not only causes loss of reagent, but also further loss on account of the poor extraction of the soluble elements desired. Also, in the case of ores of a talcose or slimy nature the talcose portions in the form of slimes prevent percolation of the solutions in tanks by clogging. These slimes should be separated and filtered separately by known methods. Then the remaining portion will easily allow percolation.

The object of this invention is to provide an improved apparatus for the purpose of overcoming these difficulties; and with this object in view the invention consists, primarily, in a hollow truncated cone mounted to rotate about a central horizontal axial line, provided with an opening at one end to receive the material to be acted upon, an opening at the opposite end to receive the fluid solvent, means for actuating the material through the cone in one direction and means for actuating the fluid solvent through the cone in the opposite direction simultaneously with the passage of said material.

706472—August 5, 1902. A. E. Johnson. *Filter bed for chlorination barrels.*

The combination with a chlorination barrel or tank of a filter bed placed therein and composed of a series of bars placed side by side and having grooves in their sides forming spaces for filtering material, the corners of the bars being cut away to permit insertion of the filtering material after the bars are placed side by side, and binding strips located at the ends of the bars and covering the filling openings, the said strips being secured to the barrel to hold the filter in place, an outlet being formed in the barrel below the filter.

708494—September 2, 1902. J. Randall. *Apparatus for extracting metals from ores.*

In an apparatus for treating ores, the combination of a series of tanks with a series of agitators above said tanks and discharging into the same, so arranged that the overflow of the solvent fluid from each tank discharges into the agitator over the next adjacent tank and from thence into the latter, and means for conveying the ore from the bottom of each of said tanks into the agitator directly above the adjacent tank for discharge into the latter.

709135—September 16, 1902. J. Brown. *Ore leaching apparatus.*

An apparatus for leaching ores, comprising a tank adapted to contain water or other liquid, a conduit connected to and extending upwardly from the tank and having the plurality of chambers, a hopper disposed above the upper chamber, ball valves for controlling the discharges of the chambers and hoppers, electro-magnets disposed above the valves and adapted when energized to raise the same, the hoods and deflectors arranged in the chambers and hopper above the electro-magnets, an electro-generator, a movable commutator and circuit wires connecting the magnets generator and commutator, the said commutator being adapted to change the circuits and the condition of the magnets.

709593—September 23, 1902. D. C. Boley. *Apparatus for treating pulverized ores of gold or silver.*

The difficulty which has been experienced in treating finely divided ores by filtration with a cyanide solution is well known. In the case of battery slimes, which are produced by crushing the ore in the battery in the presence of either water or a cyanide solution, and equally in the case of the fine dust which is produced by dry crushing and which becomes a slime by the addition of moisture, the difficulty in all these arises when attempt is made to filter the material, so as to draw off the moisture, because the slimes collect upon the surface of the filter, and when this collection reaches a certain thickness the fluid will no longer pass through and the filtering surface must then be cleaned, and this difficulty begins very soon and constantly increases as the filtering proceeds. Attempt has been made to overcome this to some extent by producing a vacuum at the delivery side of the filter, and also an attempt to facilitate the filtration by creating an air pressure on the other side of the filter; and it has been attempted to prevent the collection of this impervious coating of filtrates by stirring and agitating the contents of the filter. So far there has been no organized apparatus capable of carrying on this work of filtering slimes successfully and economically, and such an organized apparatus is the object of the present invention, which consists in a revolving filter cylinder having vacuum chambers and means for supplying air pressure, the filtering surface being arranged in cylindrical form inside of the vacuum chambers, and the mode of operation being to agitate the pulverized ore by revolving the cylinder and by the pressure of compressed air and dissolving the gold and the silver in the presence of a solution of potassium cyanide and of the oxygen derived from the compressed air and the removal of the solution containing the gold and silver by filtration, assisted by the vacuum, and the continuous removal of the filtrates from the surface of the filter by their own gravity in the turning of the cylinder and the further cleaning of the filter surface by a back-

ward blast of compressed air applied after the filtering therethrough ceases.

710462—October 7, 1902. R. D. Jackson. *Settling tank.*

In a settling tank, a distributer having downwardly extending discharge outlets for pulp and liquid, means for supplying material to said distributer, means for rotating said distributer, and means for raising said distributer while rotating, whereby the distributer rises steadily above the accumulating deposit.

710495—October 7, 1902. S. T. Muffly. *Apparatus for treating ores.*

An apparatus for treating ores, comprising a rotary cylinder, air inlet and outlet pipes connected therewith at opposite ends thereof, automatic valves oppositely directed and controlling the inlet and outlet pipes, means for forcing air through the said inlet pipe, means for heating the said air, a solvent container connected with the air inlet pipe whereby the solvent is forced by and with the air into the rotary cylinder in the form of a spray, means for governing the amount and pressure of air and of the solvent, devices within the cylinder for scattering and agitating the ores as the said cylinder is revolved.

711236—October 14, 1902. H. Smith and P. C. Brown. *Apparatus for use in extracting precious metals from their ores.*

In a lixiviation apparatus, a revoluble tank, pipes conducting a solvent, air, and steam to the tank, means for rotating the tank, and a pipe in the end of the tank opposite the end containing the supply pipe.

712963—November 4, 1902. J. J. Prindle. *Barrel filter.*

In a chlorination barrel filter, a platform comprising a series of perforated members or sections having the end portions thereof thickened or enlarged, said enlarged portions provided on their lower sides with prolonged curved faces forming supporting heels which conform to the curvature of the barrel in which the filter platform is adapted to be used, and bolts passing through said curved heels and cooperating therewith in holding the platform in place.

713694—November 18, 1902. J. P. Schuch, Jr. *Ore mixing machine.*

An ore mixing machine, comprising the following elements: An ore mixing tank, a false bottom including a strainer, means for discharging air beneath the strainer to keep the meshes thereof free from any accumulation of slime or the like, air supply pipes disposed above the strainer to effect aeration of the contents of the tank, a track carried by the upper outer portion of the tank, an agitator shaft having its upper portion polygonal in cross section, a spider having a hub engaging the said polygonal portion and carrying traveler wheels at its extremities to engage the track, agitator bars suspended from the spider, and beaters or stirrers carried by the bars, each set of beaters being disposed in break-joint order with relation to the adjacent set of beaters.

714822—December 2, 1902. J. Randall. *Settling tank or decanting vessel.*

A settling tank, consisting of a body having a vertical side and a bottom formed of slopes of different inclinations and provided with a central outlet, the said side having a cutaway portion forming an overflow lip, a launder encircling said lip and provided with a discharge spout, a baffle plate of cylindrical form connected by strips to the upper portion of said side and extending into the tank below the top and nearly to the lower edge of said side, and a pipe leading from said central outlet.

718680—January 20, 1903. B. Tully. *Barrel filter.*

A filter, comprising a rotatable barrel, provided with a lead lining, the body of the barrel being provided with apertures and the lining being perforated opposite said apertures, a lead launder arranged on the exterior of the barrel and provided with a plurality of lead branch pipes, said branch pipes at their inner ends being fitted in said apertures and connected to the lead lining about said perforations.

719273—January 27, 1903. Z. B. Stuart. *Apparatus for treating ores.*

A tank having an open top and a concave bottom formed of perforated removable plates, a removable, conical plate upwardly projecting from the center of the bottom, a perforated box under said conical plate, a layer of coarse fabric surrounding said perforated box, a filtering material under said perforated plates, a pump, a suction pipe extending from said pump to and through the mixture in said tank to a point adjacent to the upper surface of the mixture, and a discharge pipe extending from said pump to a point adjacent to the conical part in said tank, a vacuum tank, a pipe connecting said vacuum tank to said perforated box, and a suction pump connected to said vacuum tank.

719664—February 3, 1903. J. B. Heffernan. *Chlorination barrel.*

In a chlorination barrel, a parallel series of pipes having numerous small orifices through their longitudinal walls, one or more headers adapted to receiving the ends of said pipes, a valve or valves connecting said header or headers with an outside source of fluid pressure.

719756—February 3, 1903. S. C. C. Currie. *Mechanism for mixing and storing liquids and gases for ore treatment.*

In combination, an alkali mixing tank, an alkali stock tank at a lower level and connected by a pipe thereto, a mixing chamber at a level below the alkaline storage tank, said mixing chamber having inclines leading from opposite sides, a chlorin gas supply pipe leading from above the top of the mixing chamber into the bottom thereof, a storage tank for chlorinated liquid below the level of the mixing tank, and a gas supply pipe leading from the top of the mixing chamber nearly to the bottom of the storage tank.

722314—March 10, 1903. L. H. Mitchell. *Discharge means for tanks.*

A discharge apparatus for tanks, provided with a casting having an upwardly projecting rim provided with shoulders having longitudinally inclined underfaces, a funnel having a base provided with a depending offset portion, a gasket mounted in the recess formed by said offset portion and adapted to seat upon the top of the rim, lugs formed on the depending portion and provided with longitudinally curved upper faces to engage the inclined faces of the shoulders, and operating handles at the top of the funnel.

722399—March 10, 1903. H. R. Cassel. *Barrel filter.*

A barrel filter composed of a barrel having a lead lining, and of a filter having rigid cores and surrounding lead casings made integral with the lining.

725549—April 14, 1903. H. R. Ellis. *Centrifugal lixiviating machine.*

In a centrifugal filtering machine, the combination of a rotary shaft, a drum mounted thereon, a perforated partition within the drum, arranged concentrically with the periphery of the drum at such distance therefrom as to form an annular chamber about the perforated partition, means for supplying liquid to the annular chamber, a discharge opening in the bottom of the drum, a cover therefor adapted to be held open by centrifugal force when the drum is rapidly rotated to permit discharge of the charged liquid, and to be held in closed position when the drum is rotated slowly, and a discharge gate in the bottom of the drum at a point nearer the center than the discharge opening.

727230—May 5, 1903. F. G. Underwood. *Leaching tank filter.*

The apparatus consists of a tank having a central discharge aperture provided with a movable closure, an interior filter diaphragm spaced from the bottom of the tank and having a central discharge aperture registering with the tank discharge aperture and provided with a movable closure, in combination with vertical filter members radially disposed and spaced apart between said discharge apertures and the walls of the tank and communicating with the space beneath the diaphragm.

727362—May 5, 1903. H. Hirsching. *Apparatus for treating ores.*

An ore treating apparatus including a leaching vessel, a settler, a filter, a still, a condenser containing a coil, a stock solution tank, and an absorption tank, said absorption tank consisting of an outer casing communicating with a cooling water tank, an inner casing spaced from the outer casing and communicating with the stock-solution tank, and an innermost casing spaced from the inner casing and communicating with the coil of the condenser, whereby the vapors and fluid emerging from the coil are caused to flow through the innermost casing and through the absorption water, and the absorption water is caused to flow through the inner casing to the stock solution tank, said parts being connected together by means of pipes.

728126—May 12, 1903. P. W. McCaffrey. *Precipitating apparatus.*

In precipitating apparatus, the combination of a tank having curved walls, said tank being adapted to hold the solution to be treated and being provided with a central partition around the extremities of which the liquid is free to circulate, blocks or pieces made fast to the opposite sides of the tank, their inner surfaces being parallel with the surfaces of the partition, and cylinders mounted to rotate on opposite sides of the partition and partially immersed in the solution, said cylinders being perforated and containing scrap iron, the ends of the cylinders being located as close to the partition and the said blocks as is practicable in order to allow perfect freedom of movement, and means for rotating the cylinders in reverse directions whereby the liquid is set in motion in a circular current.

728746—May 19, 1903. P. W. McCaffrey. *Means for precipitating dissolved metals.*

In precipitating means, the combination of a tank adapted to hold the liquor from which the precipitation is to be made, a number of perforated cylinders containing scrap metal, said cylinders being mounted to rotate in said tank which is constructed to receive solution at one end and discharge it at the opposite end above the lowest part of the cylinders, the latter being arranged in successive order from the feed to the discharge extremity of the tank and partially immersed in the solution, and suitable means for producing a current of liquid through the tank from end to end, whereby the contact of the liquid with the scrap metal in the tanks is facilitated.

729805—June 2, 1903. J. Stoveken and L. Stoveken. *Apparatus for extracting metals from ores.*

In an apparatus for extracting precious metals from their ores, the combination of a tank for containing a cyanide or other suitable solution, means for reducing ore to a finely divided or comminuted state, one or more conduits connected with the solution tank and arranged to supply the ore with solution incident to the reduction thereof, means for agitating and mixing the ore and solution, arranged to receive the same from the reduction means, a filter arranged to receive the ore and solution from the agitating and mixing means, and adapted to separate the solution from the ore, one or more decanting tanks arranged to receive the solution or solutions from the filter, a precipitating tank which receives the clear solution from the decanting tank or tanks, and means for transferring the solution from the precipitating tank back to the solution tank.

729806—June 2, 1903. J. Stoveken and L. Stoveken. *Agitation tank.*

The combination of a tank, a central, vertical cylinder arranged therein, a piston movable in the cylinder and having a rod extending through the upper head thereof, a gear disposed above the tank and adapted to be connected by a driving connection with a motor, a shaft stepped on the piston rod and keyed to and adapted to move vertically through the gear, wings connected to and extending inwardly from the vertical wall of the tank, agitating means carried by the said shaft and surrounding the upper end of the cylinder, and comprising a head fixed on the shaft, blades disposed below the wings and connected together, said blades being curved in the direction of their length and inclined in the direction of their width, connections between the outer portions of the blades and the head on the shaft, connections between the inner portions of the blades and said shaft, and a pipe communicating with the cylinder below the piston and adapted to be connected with a source of fluid pressure supply.

730195—June 2, 1903. J. Stoveken and L. Stoveken. *Metallurgical filter.*

In an apparatus for extracting precious metals from their ores, the combination of a filter comprising a frame, an endless filter cloth, means for driving same, means for pressing pulp against the upper stretch of the cloth at different points and separate receptacles arranged below the cloth at such points, and a decanting vat having separate tanks connected with the said separate receptacles of the filter; the said separate tanks communicating with the vat at their upper ends, and having valved discharges at their lower ends.

730384—June 9, 1903. W. H. Motter. *Agitating apparatus.*

The combination of a rocking platform, means for operating the same, a frame mounted to reciprocate adjacent to the platform, cylindrical tanks or vats trunnioned on the frame and engaging the platform, flexible devices connected with the opposite extremities of the frame, guides therefor, a liquid containing tank, a piston therein, stems protruding from the opposite extremities of the tank, and a valve controlled conduit connecting the opposite extremities of the tank, the flexible devices of the frame being connected with the piston stems.

730385—June 9, 1903. P. W. McCaffrey. *Apparatus for the precipitation of metals from solutions.*

In apparatus for the precipitation of dissolved metallic values, the combination of a tank adapted to hold the solution to be treated, and a perforated receptacle containing scrap metal, the perforated walls of the said receptacle being composed entirely of the same material, said receptacle being partially immersed in said solution and mounted to rotate therein, whereby the solution is made to circulate through the scrap metal for the purpose set forth.

732720—July 7, 1903. H. Duncan and R. R. Sherriff. *Apparatus for separating liquids from solids.*

A machine for separating liquids from solids, comprising in combination a framing and gear, carrying and traversing an endless band of filter cloth, automatic slip devices for securing the band, a vacuum box or suction chamber located upon the under surface of said band, and an interposed endless band of wire cloth or gauze arranged to support and travel with the filter band.

733739—July 14, 1903. F. H. Officer, R. H. Officer, J. H. Burfeind, and J. W. Neil. *Apparatus for use in metallurgical processes.*

In an apparatus for treating ores or other materials containing gold or silver or other metals by the cyanide process, the combination of a treating tank, an absorption tank containing a caustic solution, a compressor and connections as described between the compressor, treating tank and absorption tank whereby air or gas under pressure may be forced from the compressor through the material in the treating tank and the gases released or freed from said material may be passed through the absorbing solution in the regenerator tank and thence to the compressor, so as to permit the air to be used over and over and the valuable products released in the treating tank to be recovered, as and for the purpose described.

735206—August 4, 1903. L. P. Burrows. *Mixing and dissolving apparatus.*

A mixing and dissolving apparatus, comprising a containing vessel, a shaft in and movable relatively to said vessel, an inner and an outer set of stirring plates carried by and arranged around and substantially parallel to said shaft, the adjacent plates of the inner and outer sets converging toward each other from their front to

their rear edges, and stirring blades secured to the rear edges of said plates and arranged in a spiral line around the shaft, the corresponding blades of the outer and inner sets being twisted in opposite directions.

735834—August 11, 1903. L. B. SKINNER. *Filter.*

A filter bar, consisting of a body portion and separated tongues projecting laterally therefrom and recessed for the passage of filtering fluid, each tongue with a beveled end, and beveled faces on the body between the tongues.

735835—August 11, 1903. L. B. SKINNER. *Filter.*

The combination in a filter bed, of bars having each a body portion and a perforated side flange with a beveled edge, and a beveled face constituting the bearing of the flange of the adjacent bar.

735960—August 11, 1903. G. S. FOSTER and S. S. D. STRINGER. *Metal-extracting and ore-lixiviating apparatus.*

The combination of a solution-supply tank, a series of intercommunicating leaching tanks adapted to receive solution from said supply tank, drainpipes leading from said leaching tanks, a launder into which said drainpipes are arranged to discharge, and a charcoal box connected to said launder.

736036—August 11, 1903. H. L. SULMAN and H. F. KIRKPATRICK-PICARD. *Apparatus for the recovery of precious metals.*

In an apparatus for recovering precious metals, the combination of a conical vessel having an inner amalgamated copper surface, a conical body having an outer amalgamated copper surface disposed concentrically within the vessel and forming therewith a narrow interspace, a body of mercury charged with an electropositive metal in the interspace, an electrolytic vessel for charging the mercury, a mercury pump, an inlet conduit to the top of the interspace from the electrolytic vessel, an outlet conduit for mercury from the bottom of the interspace to the pump, a conduit from the pump to the electrolytic vessel, an inlet conduit at the bottom of the vessel for the solution carrying the values, a nonreturn valve in said conduit, means for forcing the solution up through the interspace, and a launder at the top of the vessel to receive the discharged solution.

736078—August 11, 1903. H. T. DURANT. *Apparatus for the treatment of ores with solvents.*

A device for the treatment of ore, tailings, or other material by solvents, consisting of a tank having a conical bottom, a plug in said bottom and made conical to correspond to the angular walls thereof, a pump or forcing device discharging into the apex of the cone, and a return connection between the upper part of the tank and the suction of the pipe.

736597—August 18, 1903. C. D. GROVE. *Barrel filter.*

In a barrel strainer, the combination with the shell thereof of a strainer the exterior surface of which is in contact with the barrel, its inner surface being provided with suitable straining perforations in the form of slits combined with transverse grooves beneath the interior surface and establishing communication between said slits and the discharge opening.

737046—August 25, 1903. J. B. TRUITT, W. L. TRUITT, and W. O. TEMPLE. *Precipitating zinc box.*

In a precipitating zinc box, the combination of an outer imperforate box having a valved outlet in its bottom and a valved outlet above its bottom, a launder at each outlet, and an inner removable zinc holding box having a perforated bottom, and supported in the outer box above the bottom of the latter.

737533—August 25, 1903. E. L. V. NAILLEN. *Apparatus for extracting gold and other metals from ores.*

In an apparatus for extracting metals from ores, the combination of a concentrating tank consisting of two cone shaped sections secured together at their largest diameter by means of suitable flanges and provided with an intermediate strip secured between said flanges and projecting outwardly, a settling tank disposed around the concentrating tank, a perforated diaphragm placed between the concentrating and settling tanks and supported upon said intermediate strip, and a suitable bracket bolted to the settling tank and adapted to form two horizontal sections within the settling tank.

738148—September 8, 1903. J. B. DE ALZUGARAY and W. A. MERCER. *Apparatus for extraction of precious metals from their ores.*

Apparatus for treating ores, consisting of a closed containing vessel or vat provided with fixed internal blades or wings, a rotating hollow spindle provided with ball bearings and having hollow blades or beaters set at an angle, means for raising and lowering the spindle in the vat, gearing for rotating the spindle, and means connected with the vat for supporting the gearing and steadying the spindle, all combined, arranged, and operating as shown and described and for the purpose set forth.

738329—September 8, 1903. W. E. HOLDERMAN. *Device for treating slimes.*

In a device for treating slimes having a liquid-tight case, a discharge pipe provided with a valve in its bottom, an inclined floor in said case, spaced bars on said floor and the sides of the case, a filtering fabric covering said bars and overlapping the upper edge of the tank, a molding to hold the fabric in operative position, and pipes provided with stoppers leading from the filter out through said case.

740193—September 29, 1903. E. D. SLOAN. *Barrel filter.*

In a barrel filter, the combination with the barrel of a partial lining of porous filter blocks fitting closely together and having grooves formed on their undersides which interconnect from block to block and form drain channels; means for sealing said draining channels from the inner space of the barrel, and a discharge port leading from the drains out of the barrel.

741189—October 13, 1903. H. H. THOMPSON. *Apparatus for extracting precious metals.*

An apparatus for extracting precious metals, comprising a receptacle provided with an outlet, a series of bodily movable and loosely mounted agitating arms gradually decreasing in length and adapted to be retained in their operative position when rotated in one direction and to assume an inoperative position when moved in an opposite direction, a rotatable means for suspending said arms within said receptacle, said rotatable means and arms bodily movable, a series of screened nozzles communicating with said receptacle, means for supplying a cyanide solution, compressed air and water to each of said nozzles either separately or in any preferred combination, operating means for said rotatable means, and means communicating with said supply means and the said outlet for exhausting the solution from said receptacle.

741402—October 13, 1903. W. E. HOLDERMAN. *Leaching tank.*

In a filtering tank having vertical slats covered with a filtering fabric, a filtering partition extended across said tank, a trough in its bottom for the filtrate, and an orifice through the filtering fabric of said tank into which the filtrate from said trough is discharged.

741499—October 13, 1903. A. E. JOHNSON. *Barrel filter.*

In a barrel filter, the combination with a suitable barrel or cylinder, of a filter having a perforated bottom, side walls extending below the bottom and engaging the barrel on the inside, filtering material resting on the bottom and confined by the side walls, a top perforated plate, and suitable means for securing the filter in place, a channel being formed underneath the bottom of the filter to receive the filtered liquid, the barrel being provided with a valved outlet in communication with the said channel.

743550—November 10, 1903. J. A. OGDEN. *Process of extracting metals from cyanide solutions.*

The process of treating gold, silver, or other metals from a cyanide or primary solution, consisting in mixing in a receptacle a

given quantity of said primary solution with a given quantity of a secondary solution having a metal base and capable of liberating the metals in said primary solution; leaving said mixture in said vessel until said liberation is partially effected, then passing said mixture into a second receptacle and agitated therein so as to produce a complete commingling of said solutions, from thence running the mixed solution into a settling tank and allowing it to settle, drawing off the clear solution, and then drying the precipitation and pressing and melting it into bullion.

743551—November 10, 1903. J. A. Ogden. *Apparatus for extracting precious metals from cyanide solutions.*

An apparatus for the purpose set forth, consisting of primary and secondary solution tanks, each provided with discharge pipes with controlling cocks, and measuring glasses; a mixing vessel adapted to receive the flow from said measuring glasses; a barrel, with rotatable blades therein, and having a glass gauge on the outer face thereof, and a settling tank adapted to receive the discharge from said barrel.

745472—December 1, 1903. W. H. Adams, Jr. *Apparatus for treating ores.*

The combination of a tank, a box, a pipe at the top of the tank connecting the same with the box, a pump connected with the box, and nozzles connected with the pump and arranged to discharge liquid into the tank at intervals tangentially in an approximately horizontal plane.

746867—December 15, 1903. De W. C. Mosher. *Chlorination barrel.*

A chlorinating barrel provided with a resistant lining and with an arched channeled rib extending longitudinally, secured to said lining and having perforations between the interior of the rib and barrel, and a discharge opening communicating with the interior of the rib.

748088—December 29, 1903. G. Moore. *Filtering system.*

In a filtering system, the combination with a tank for containing the material to be filtered and a cleansing fluid tank, of a filter, means for introducing and removing the same into and from each of said tanks alternately, means for drawing the contents of said tanks through the filter, and means for cleansing the filter.

748217—December 29, 1903. C. H. Rider. *Apparatus for dissolving organic or inorganic substances.*

A device consisting of an acid tank, a water tank, an upper series of tanks connected with the acid tank and the water tank and to each other, a lower series of tanks adapted to receive the substance to be treated, connected to the upper series of tanks and to the water tank and to each other; a retort, means for heating the retort, a pipe passing from the retort through the lower series of tanks, and a condenser into which the last-named pipe extends, substantially as and for the purposes specified.

748462—December 29, 1903. W. J. Armbruster. *Chlorination barrel.*

A chlorination barrel having a pulp chamber and a chlorine generating compartment rotatable therewith, a wall separating the pulp chamber from the compartment, said wall having an unobstructed opening disposed about the axis of rotation of the barrel for freely permitting the discharge of the chlorine above the surface of the pulp in the pulp chamber.

CLASS 75—METALLURGY.

Subclass 185—Cyanides.

323222—July 28, 1885. J. W. Simpson. *Process of extracting gold, silver, and copper from their ores.*

The ore is crushed to a powder, treated with a solution produced by dissolving 1 pound of cyanide of potassium, 1 ounce of carbonate of ammonia, and one-half ounce of chloride of sodium in 16 quarts of water when the ore contains gold and copper only; but when it is rich in silver the quantity of chloride of sodium employed is increased. After thorough agitation of the ore in the solution the mixture is allowed to stand until the solution has become clear, when the dissolved metals are precipitated out by means of a plate of zinc suspended in the liquid. The metal is precipitated upon the zinc and can be removed by scraping or by dissolving the zinc in sulphuric or hydrochloric acid.

403202—May 14, 1889. J. S. MacArthur, R. W. and Wm. Forrest. *Process of obtaining gold and silver from ores.*

The invention consists in subjecting finely-powdered argentiferous ores to the action of a solution containing a small quantity of a cyanide, the cyanide contents of the latter being proportioned to the quantity of gold or silver, or both, found, by assaying or otherwise, to be in the ore. Any cyanide soluble in water may be used, but in all cases the solution must be extremely dilute, since such a solution has a selective action in dissolving gold or silver in preference to the baser metals. The claim covers the use "of a cyanide solution containing cyanogen in the proportion not exceeding 8 parts of cyanogen to 1,000 parts of water."

418137—December 24, 1889. J. S. MacArthur, R. W. and Wm. Forrest. *Process of separating gold and silver from ore.*

This invention has for its object the preventing of loss of cyanide in the case of weathered ores by first neutralizing the ore with an alkali or alkaline earth and then leaching such prepared charge with a cyanide solution. Further, the precious metal thus dissolved in the cyanide solution is precipitated out by passage through a sponge of zinc composed of fine threads or filaments of zinc formed by cutting shavings with a turning tool from a series of zinc disks held in a lathe, or by passing molten zinc at a temperature just above the melting point through a fine sieve and allowing it to fall into water.

482577—September 13, 1892. E. D. Kendall. *Composition of matter for the extraction of gold and silver from ores.*

Consists in extracting gold and silver from minerals, "tailings," and other matters containing one or both of these metals by an aqueous solution of one or more soluble ferricyanides and one or more soluble cyanides prepared by dissolving a ferrocyanide in one portion of water and a cyanide in another portion and mixing the two solutions, or by adding either salt in solid form to the solution of the other.

492221—February 21, 1893. C. Moldenhauer. *Extracting gold from its ores.*

Consists in subjecting gold ores to the solvent action of cyanide of potassium in the presence of ferricyanide of potassium.

494054—March 21, 1893. W. A. G. Birkin. *Process of and solvent for separating precious metals from their ores.*

Covers the art of separating metals from their ores by subjecting the suitable comminuted ore to the action of a menstruum composed of potassium cyanide, potassium ferricyanide, and peroxide of hydrogen in water, and separating the values from this solution by precipitation, deposition, or electrolysis.

496950—May 9, 1893. H. Parkes and J. C. Montgomerie. *Process of extracting gold or silver.*

Claims a process for extracting gold and silver from ores or compounds by an interrupted operation, consisting of treating the ore with cyanide of potassium in the presence of oxygen under pressure with agitation, the ore being subsequently filtered and washed and the precious metals recovered from the liquor by precipitation or other known means.

514157—February 6, 1894. W. P. Miller. *Process of recovering precious metals.*

Has for its object the preservation of the cyanide solution, and consists in the treatment of the ore with the cyanide solution in air-tight vessels not only during the process of solution, but during

the filtration and up to the time of the precipitation of the precious metals from the filtered solution.

522739—July 10, 1894. C. Moldenhauer. *Process of precipitating gold or other precious metals from their solutions.*

Dissolves gold and other precious metals from their ores by means of acid cyanide solutions, which consist in treating the solution with aluminum, so as to precipitate the gold from the solution, and then add a free alkali or alkaline earth for a regenerating solution.

524601—August 14, 1894. J. C. Montgomerie. *Process of extracting gold or silver from ores.*

Sodium oxide (caustic soda) or other suitable oxide of the alkalies is added to the cyanide solution before mixing the same with the ore. After the precious metals have been dissolved in the solution and the liquid filtered off and the precious metals precipitated out, the remaining solution is tested to determine the quantities of potassium and sodium oxide still remaining in it, and any deficiency is supplied or the solution fortified by the addition of the necessary quantity of these agents, so as to restore the solvent solution to its original character and strength.

524690—August 14, 1894. E. D. Kendall. *Method of treating gold or silver ores.*

Covers the treating of gold or silver ores with a composition of matter consisting of sodium dioxide and a suitable cyanide in solution.

532238—January 8, 1895. C. Moldenhauer. *Method of precipitating precious metals from solutions.*

Consists in subjecting the ores to the action of an acid cyanide solution so as to dissolve the gold or other precious metal contained in them, then adding aluminum so as to precipitate the gold or other metal from the solution, and then regenerating the cyanide solution by means of a free alkali or alkaline earth.

532895—January 22, 1895. J. C. Montgomerie. *Process of extracting gold or silver from ores.*

Consists in adding an oxide or one of the alkaline bases to a cyanide solution, then mixing with the ore or compound the solution thus rendered alkaline, then conducting the process under pressure of oxygen, and afterwards separating from the ore the liquid containing the gold and silver in solution, then treating that liquid in any approved way for the recovery of the precious metal.

538951—May 7, 1895. S. C. Clark. *Process of treating refractory ores.*

Claims the process of treating a refractory ore, consisting essentially in boiling the ore in water containing from 10 to 15 pounds of cyanide of potassium to each ton of ore for about one hour or for a sufficient length of time to enable the cyanide of potassium to dissolve the chloride, sulphide, or bromide in the ore, then allowing the solution to settle and finally evaporating the clear liquid so as to obtain a residue containing metal.

540359—June 4, 1895. G. Kennan. *Process of and apparatus for treating ores.*

Claims the process of treating the ores of gold and silver, consisting in subjecting the same to the action of cyanide of potassium, agitating the same for a short period of time, discontinuing the agitation, and bringing air in contact therewith, the oxygen thereof increasing the action of the cyanide, continuing the agitation for a few minutes, until every particle of ore has been brought in contact with the cyanide solution in the presence of atmospheric air, and withdrawing the solution from the remaining pulp or ore.

541333—June 18, 1895. F. Rinder. *Process of separating gold and silver.*

Consists in the treatment of cyanide solutions containing gold and silver with sulphide of iron to precipitate the silver and then with chloride of zinc to precipitate the gold.

543543—July 30, 1895. M. E. Waldstein. *Process of extracting gold or silver from ores.*

Consists in subjecting the ores to the action of cyanide of potassium, adding to the material during this action a salt or salts (such as binoxide of barium) decomposable by an acid and yielding oxygen, and sufficient acid to decompose this salt or salts, and subsequently adding an excessive acid to decompose the soluble cyanide and finally separating the precious metals as sulphides by precipitation with sulphureted hydrogen or by a soluble sulphide.

543672—July 30, 1895. M. Crawford. *Process of extracting precious metals from their ores.*

Consists first in lixiviating the ores of the precious metals with a cyanide solution to which has been added a substantially neutral substance which contains a permanent excess of oxygen; second, in subjecting the gangue and accompanying cyanide solution to an amalgamating process; and, thirdly, in withdrawing the solution from the tailings, and extracting the precious metals therefrom. The neutral substance containing a permanent excess of oxygen may be prepared by mixing peroxide of sodium with dilute sulphuric acid and neutralizing with silicate of soda.

543676—July 30, 1895. M. Crawford. *Process of extracting precious metals from their ores.*

Consists in, first, lixiviating the ore with a cyanide solution to which has been added a small quantity of a substance prepared by agitating ether with binoxide of barium and adding thereto small quantities of very dilute hydrochloric acid, and neutralizing by silicate of soda, and, second, separating the precious metal from this solution in which the ore has been lixiviated.

545852—September 3, 1895. P. de Wilde. *Method of extracting gold.*

The precipitation of gold in the form of a mixture of aurous cyanide and cuprous cyanide by acidulating a cyanide solution containing the gold with an acid sulphurous compound and afterwards adding a solution of copper salt. Also, specifications provide for the dissolving of gold by the use of a weak solution of potassium or sodium cyanide which has been in contact with the minimum or protoxide of lead, and for the recovery and utilization of the spent cyanide by its conversion to Prussian blue.

547790—October 15, 1895. J. J. Hood. *Extracting metals.*

The method for the extraction of precious metals from their ores, which consists in treating the ore with a solution containing both a cyanide of potassium or sodium and a salt or compound of a baser metal in the proportion of one part at least of the former to two parts of the latter; the metallic base of the solution being displaced by the precious metal, the former being precipitated. The gold is then precipitated out by a copper-zinc couple. By "baser metal" is meant mercury, lead, and such other metals as are displaced by metallic gold from their solutions in alkaline cyanides. A mixture that answers well consists of two parts, by weight, of cyanide of potassium (or its equivalent of cyanide of sodium), one part of mercuric chloride or its equivalent of sulphate or other mercury salt, and from one-half to two parts of caustic soda.

549736—November 12, 1895. J. C. Montgomerie. *Extraction of gold and silver from ores.*

The improved process of extracting gold and silver from ores or compounds containing the same, consisting in treating the ore in a vessel containing water with a cyanide, an alkaline oxide, a nitrate, and an oxidizing agent. Sodium dioxide may be taken as a representative of the alkaline oxide and aid under pressure as an oxidizing agent, as set forth in this claim.

555463—February 25, 1896. J. S. MacArthur and C. J. Ellis. *Process of extracting gold and silver from ores.*

Consists in subjecting the ore to the action of a cyanide solution and precipitating, by means of a metallic compound capable of com-

bining with sulphur, any sulphur which may become soluble in the solution and thereby rendering it inert. Salts or compounds of lead, manganese, zinc, mercury, and iron are types of the metallic compound employed. By means of a salt of lead any copper present in the cyanide solution may be precipitated out.

555483—February 25, 1896. T. L. Wiswall and J. B. Frank. *Process of recovering precious metals from solutions.*

The process of extracting precious metals from solutions by causing said solutions to flow through a precipitating alloy, subdivided into a mass of hardened filaments, and composed of zinc, lead, and one or more other metals which impart to said filaments a tensile strength sufficient to withstand the compression of the flowing solution, such as arsenic, antimony, cadmium, or bismuth, and in which alloy there is present not more than 97 per cent of zinc.

576173—February 2, 1897. H. L. Sulman. *Process of precipitating precious metals from their solutions.*

Consists in purifying zinc fumes or dust of oxides by intimately mixing with the same an ammoniacal substance, and then mixing a quantity of said fumes or dust so purified with the solution. The apparatus by which to perform the process and for the treatment of the ores is also claimed.

578089—March 2, 1897. J. F. Webb. *Process of extracting gold and silver from ores.*

The process or method for the extraction of gold and silver from their crushed ores, consisting in saturating the ores in a solvent solution of potassium cyanide, then applying a current of compressed air from beneath and maintaining the same throughout the leaching process, then shutting off the current, then applying a current of compressed air on top of the solution after the ore containing vat has been closed at top and a drain at the bottom has been opened, and maintaining the same until the solution has been driven out of the ore, then shutting off the current of air, then admitting water to the vat, then introducing a compressed air current at the bottom of the vat, and finally introducing a current of compressed air on top after the vat has been again closed at top and a drain opened at bottom.

578178—March 2, 1897. D. White and T. M. Simpson. *Process of and apparatus for extracting precious metals from slimes, etc.*

In the extracting of precious metals from slimes and other auriferous and argentiferous materials, the process which consists in mixing the said material with a cyanide solution in a closed vessel, then agitating the mixture by passing a gas under pressure through the same, then passing gas under pressure, together with the gases arising from the action of the cyanide solution in the said material, through another quantity of said material and cyanide solution in a closed vessel, then conveying the gases back to the source of compression and drawing off the solution containing the precious metal and extracting said metal. The apparatus for accomplishing this purpose is also claimed.

578340—March 9, 1897. W. A. Koneman. *Process of extracting precious metals from their ores.*

The process of extracting precious metal from the ore containing it, which consists in wetting the ore, in a pulverized condition, with just sufficient cyanogen-containing solution to moisten the ore and reduce the mass to the condition of mud, maintaining the saturated ore in a quiescent state for a prolonged period of time, then diluting the mass and subjecting it to agitation for a suitable period of time, separating the resultant solution from the ore by filtration, and finally precipitating the precious metal from said solution.

578341—March 9, 1897. W. A. Koneman. *Process of recovering precious metals from cyanide solutions containing them.*

The process of recovering, by precipitation, the precious metal or metals contained in a cyanogen-containing solution, which consists in subjecting said solution to contact with an alloy composed of lead and zinc, and in which lead is the preponderating metal in weight, or with an alloy composed of lead, zinc, and aluminum.

580683—April 13, 1897. C. W. H. Göpner and H. L. Diehl. *Recovery of gold and silver from their solutions.*

The process for the precipitation of gold and silver from their cyanide solutions, which consists in adding to said solutions a considerable quantity of cuprous cyanide, then adding an acid to effect precipitation, dissolving the latter by a fresh quantity of the cyanide solution obtained by leaching, and then adding acid to effect successive precipitations from said solution.

580948—April 20, 1897. J. C. Montgomerie. *Process of treating cyanide solutions.*

The process for the extraction of the precious metals from cyanide solutions, which consists in filtering the solution through a charcoal filter, heating the filtering material on the same becoming surcharged with cyanogen or its compounds, condensing the resultant gases and obtaining ammonium cyanide and other ammonium salts in solution, applying the regenerated charcoal (still containing the precious metals) in the filtration of a further charge or charges of the solution, and ultimately recovering from the charcoal the precious metals accumulated therein.

587179—July 27, 1897. J. H. Burfeind. *Treatment of gold and silver ores.*

As an improvement in the extracting of precious metals from their ores, the treatment of the cyanide product or precipitate containing said metals, preparatory to melting the said product with sulphurous acid.

591753—October 12, 1897. E. J. Fraser. *Process of obtaining precious metals by solution.*

The process of treating gold and silver ores by solution, which consists in converting the metal bases of dioxides of the alkaline metals into sulphates, by the addition of sulphuric acid, so as to produce hydrogen dioxide, preventing the decomposition of the hydrogen dioxide by an excess of acid, separating the solution from the metallic sulphate, mixing the solution with a solution of cyanide of potassium and lime in the presence of a precious metal, and leaching the liquid holding the precious metal.

592153—October 19, 1897. J. S. MacArthur. *Precipitating precious metals from solutions.*

The process of precipitating a precious metal from a cyanide solution, which consists in subjecting said solution containing a base metal to the action of a precipitant protected by a metal inert in said solution. Such a precipitant is found in zinc, mercury, or copper protected by lead. When copper is present in the cyanide solution, this copper is removed by the precipitant prior to the removal of the precious metal.

601201—March 22, 1898. S. Newhouse, A. J. Bettles, and T. Weir. *Method or process of extracting precious metals from their ores.*

A method or process for the extraction of the precious metals from their ores, said method or process consisting, first, in neutralizing the acidity of the ore where this condition exists; second, in placing the ore in a suitable solution of cyanide of potassium and subjecting the mass to agitation; third, in adding a quantity of zinc to the mixture of ore and cyanide and subjecting the mass to further agitation; and fourth, in adding quicksilver or mercury charged with sodium amalgam, and finally agitating the entire mass for purposes of amalgamation.

607719—July 19, 1898. M. E. Waldstein. *Process of recovering precious metals from their solutions.*

The process for extracting and recovering precious metals from their ores, which consists essentially of the following steps: First, subjecting the ore in a powdered state to the action of an aqueous solution of a cyanide; second, supplying to the solution charged with the precious metals that quantity of zinc dust deter-

mined to be exactly sufficient to precipitate said metals; third, agitating said solution and said zinc dust until said metals are precipitated and said zinc dust is absorbed; fourth, recovering the precious metals from the valuable precipitate of the preceding step by filtration, or other process.

610616—September 13, 1898. H. L. Sulman and F. L. Teed. *Extraction of precious metals from their ores.*

The essence of this invention consists in the employment of haloid compounds of cyanogen in combination with free cyanide of potassium or other suitable cyanide of the alkalies or alkaline earths as a solvent for precious metals in their ores, examples of such haloid compounds of cyanogen being found in cyanogen chloride, or bromide or iodide.

620100—February 28, 1899. W. A. Caldecott. *Method of extracting gold from cyanide.*

An improved method for the precipitation of gold from gold bearing cyanide solutions by passing such solutions over zinc shavings previously treated with a soluble salt of mercury, such as perchloride of mercury ($HgCl_2$).

624040—May 2, 1899. C. B. Jacobs. *Process of reducing metals from their solutions.*

The process of reducing metals from their solutions, consisting in subjecting them to the action of gaseous phosphide of hydrogen in the presence of an alkaline material, thereby precipitating the noble metals in a metallic state and the base metals as phosphides, and then separating the latter from the noble metals.

625564—May 23, 1899. E. D. Kendall. *Process of treating gold or silver ores and composition of matter for same purpose.*

A composition of matter to be used for extracting precious metals from ores, tailings, or other bodies, consisting of a suitable thiocyanate and a suitable ferrocyanide in watery solution.

625565—May 23, 1899. E. D. Kendall. *Process of treating gold or silver ores and composition of matter for same purpose.*

A composition of matter to be used for the extraction of precious metals from ores, tailings, or other bodies, consisting of a suitable thiocyanate and hydrogen dioxide in watery solution.

629905—August 1, 1899. J. J. Hood. *Process of extracting gold or silver.*

The process of extracting gold, silver, and mercury from solutions by bringing the solutions into contact with an alloy of zinc, antimony, and mercury, from time to time distilling off mercury from the alloy, and finally recovering the gold and silver from it. The precipitant used consists of an alloy of about one hundred parts of zinc, five parts of antimony, and twenty parts of mercury.

630982—August 15, 1899. W. Kemmis-Betty and B. Searle. *Process of recovering gold from pulp, slimes, or similar substances.*

The process of extracting gold from ores, which consists of the following steps: First, dissolving the gold in the pulp in a weak solution of cyanide of potassium; second, adding a stronger solution of cyanide of potassium to the gold-bearing solution in the proportions specified; third, immediately after so strengthening the solution, passing the same through a body of zinc shavings coated with lead.

635199—October 17, 1899. J. Smith. *Process of treating gold or silver ores.*

The process for treating gold and silver ores, tailings, slimes, and like materials containing precious metals, which consists in mixing the material to be treated with caustic lime, saturating or covering the mixture entirely with water and keeping it thus until all the acid present has combined with the lime, drying the material, exposing it to the action of atmospheric air, and treating it with a cyanide.

636114—October 31, 1899. J. S. Cain, A. Soderling, and S. M. MacKnight. *Preliminary treatment of ores or tailings before cyaniding.*

The method or process of treating ores containing the precious metals, which consists in first leaching said ores or tailings in a weak solution of nitric acid, or of nitric and sulphuric acids, subsequently leaching the same in an alkaline solution, and finally leaching the same in a cyanide solution.

636288—November 7, 1899. H. de Raasloff. *Process of extracting precious metals from ores.*

The improvement in the process of separating precious metals from their ores, consisting in mixing with the ore a solution consisting of a base and a solvent for precious metals, which solvent is capable of being separated from the said base by oxygen, and adding liquid air to the ore and solution, or by evaporating the nitrogen from liquid air, and adding the oxygen which remains to the mixed ore and solution.

638372—December 5, 1899. M. B. Zerener. *Precipitation of precious metals from their cyanide solutions.*

The process of precipitating gold and silver from cyanide solutions by causing the solution to move in one direction, and during such movement passing through it, in the opposite direction and in the form of a spray, or a number of fine streams or films, mercury charged with alkali metal.

641818—January 23, 1900. C. Whitehead. *Process of extracting gold from ores.*

The process of extracting gold from ores in which the particles of free gold are enveloped in a compound of a base metal having the following characteristics, to wit; nonsiliceous, oxidized, practically impervious to a solvent solution, such as one of cyanide, not readily removable by washing with water, and insoluble in water, but soluble in dilute acids, consisting in first subjecting the crushed ore to the action of heat sufficient to convert the coating into a porous condition and afterwards treating the ore with a cyanide solution.

642767—February 6, 1900. G. Thurnauer. *Process of separating precious metals from their mixtures with zinc.*

The process of treating the mixture of zinc and precious metals resulting from the treatment of cyanide solutions of the precious metals by zinc, which consists in subjecting said mixture to the action of a solution containing lead and then to the action of acid, whereby the zinc is dissolved and the precious metals remain in admixture with metallic lead.

646006—March 27, 1900. J. C. Montgomerie and H. Parkes. *Treatment of gold and silver ores, etc.*

In the extraction of gold and silver from ores or compounds containing the same, the process consisting in treating the ore or compound with a cyanide of an alkali metal, caustic alkali, and barium dioxide, in conjunction with ammonium sulphate.

646808—April 3, 1900. T. Cruse. *Method of extracting gold and silver from their ores.*

The process of recovering precious metals from their ores, which consists in first heating the ore pulp to the boiling point, adding cyanide of potassium to the hot mass, permitting the mass to gradually cool, and while it is cooling adding to the mass the following: Bluestone, iron sulphate, sulphuric acid, and quicksilver.

649628—May 15, 1900. W. A. Caldecott. *Extraction of gold or other precious metals from slimes.*

The method of extracting precious metals from finely divided materials, such as slimes, containing reducing substances, such as ferrous sulphide or hydrate, which consists in rendering the material alkaline, then forcing air into the pulp until the ferrous com-

pounds are converted into ferric hydrate, then adding cyanide and continuing aeration and agitation until the precious metals are dissolved.

651509—June 12, 1900. F. W. Martino and F. Stubbs. *Precipitation of precious metals from cyanide solutions.*

A process for the precipitation of the precious metals from their aqueous cyanide solutions, consisting in passing acetylene and atmospheric air through such solutions, or by adding calcium carbide to them, and precipitating the metals in a metallic state.

651510—June 12, 1900. F. W. Martino and F. Stubbs. *Treatment of ores and precipitation of precious metals from their cyanide solutions.*

A process for the precipitation of precious metals from their aqueous cyanide solutions, consisting in treating such solutions with a hydrocarbon gas, produced when a metallic carbide is decomposed by water, and capable of precipitating the metals in a metallic state. Aluminum carbide is given as an example of such a metallic carbide. The use of methane as a precipitant is also claimed.

657181—September 4, 1900. H. de Raasloff. *Process of separating precious metals from their ores.*

The continuous process of treating ores of precious metals, consisting in mixing the finely divided ore with a suitable solvent for the precious metals, inducing the mixture to flow continuously from and back to the point of admixture, while so flowing introducing liquid oxygen or liquefied air into the mixture, then causing the mixture to flow with sudden variations of velocity to agitate it, then separating the solution from the base earthy mineral matter, and sending it continuously through an electro-depositing bath, where the precious metal is deposited, and thus in continuous ordered succession.

656395—August 21, 1900. E. H. Dickie. *Process of leaching ores or tailings.*

The improvement in the process of leaching ores or tailings with a solution which dissolves the precious metals, which consists in adding to the solution an agent composed of an acetate of an alkali metal or of alkali earth metals which is capable of readily uniting with and forming acetates of the base metals, and which has little or no affinity for the precious metals, thereby enabling the solvent to act directly upon the latter, and then leaching the ores. Calcium acetate is cited as an example of an acetate of an alkali-earth metal.

664060—December 18, 1900. J. P. Schuch, Jr. *Process of extracting precious metals from their ores.*

A method of extracting precious metals from their ores, which consists in combining the crushed ore with a cyanide solution while both are in a warm condition, mechanically mixing the ore and solution by agitation simultaneously with the commingling thereof, charging the mixture during the agitation with hot air, and finally separating the ore and slush or pulp from the metal in solution.

665105—January 1, 1901. J. C. Kessler. *Process of extracting gold and silver from ores.*

The process of separating precious metals from auriferous and argentiferous ores, consisting, first, in subjecting the ores to the action of an aqueous solution, consisting of cyanide of alkali metal, yellow prussiate of potassium and permanganate of an alkali metal in substantially the proportions of water, one thousand (1,000) parts; yellow prussiate of potassium, two and one-half (2.5) parts; cyanide of alkali, two and one-half (2.5) parts; permanganate of potassium, one-tenth (0.1) part, until the gold and silver contained in such ores are dissolved; second, separating the metals from their solution by the application of a soluble lead salt, by which the cyanide solution is decomposed and a nonsoluble cyanide of lead is formed, at the same time a nonsoluble cyanide of gold or silver is precipitated; third, by the application, to the sediment thus precipitated, of sodium amalgam, whereby a gold, silver, and lead amalgam is produced and at the same time a concentrated solution of cyanide and ferrocyanide of sodium is regenerated; and fourth, diluting the concentrated cyanide solution with a quantity of water and regenerating and reenergizing the aqueous solution for reuse by the addition of permanganate of alkali.

671704—April 9, 1901. E. D. Kendall. *Process of treating ores containing silver or silver and gold.*

The process of treating ores or other bodies for the extraction of precious metals, which consists in treating them with a suitable chemical solution containing a thiocyanate and a cyanide, capable of dissolving silver or silver and gold, and in then treating the so-dissolved silver by a suitable sulphide, such as potassium sulphide, and in so regulating the amount of the sulphide to the silver as that they shall substantially equalize each other in separating the sulphur sulphide and in returning the thiocyanate and cyanide into subsequent operations for further treatment of the ore.

673425—May 7, 1901. G. A. Duncan and F. H. Beach. *Method of treating precious metal bearing ores.*

The method of treatment of precious metal bearing ores to cause the precious metal to be dissolved from the ore, and the resulting metal bearing liquor and impoverished ore to be separated from each other, which consists in the following steps: First, maintaining a substantially continuous supply stream of mingled comminuted ore and solvent liquor; second, mechanically dispersing such mingled ore and liquor into the air, in a direction transverse to the onward movement of the stream, without separating the ore from the liquor; third, delivering the resultant stream of mingled metal bearing liquor and impoverished ore and receiving the same in mingled condition and carrying it onward; fourth, sucking the liquor from the tailings; fifth, delivering water to the impoverished tailings remaining, and subsequently sucking such wash water therefrom; sixth, delivering such impoverished ore or tailings after the application of such suction.

682612—September 17, 1901. E. L. Godbe. *Method of leaching ores.*

The method of leaching ores, which consists in disposing moistened ore in superimposed strata within a containing receptacle by a continuous mechanical agitation in the lower portion of the latter to form a lower thoroughly agitated stratum of heavier portions of the ore, a stratum of lighter portions or particles next above which are agitated to a less degree, a stratum of slimes and other lighter particles next above which remain substantially immobile, and a top covering of a clear supernatant solution, introducing the ore below the upper surface of said latter solution, overflowing and carrying off the clear solution, replacing water in the charge by a cyanide of potassium solution introduced at the bottom of the receptacle below the lower heavier stratum and causing it to percolate upwardly through the strata above, increasing the agitation during the introduction of said cyanide solution, carrying off the metal bearing cyanide solution which overflows from the top of the charge and precipitating the said overflow metal bearing solution after it leaves the receptacle.

689190—December 17, 1901. B. Hunt. *Process of precipitating and recovering precious metals from their solutions.*

The process of precipitating precious metals, consisting of adding to the pulp a cyanide solution and agitating the same until the metal is extracted; then adding to the pulp, while continuing the agitation thereof, powdered metallic aluminum whereby the precious metal is precipitated, but in suspension in the pulp; then adding mercury and continuing the agitation until the metal is in the form of an amalgam, and finally recovering the precious metal by treating the amalgam.

692634—February 4, 1902. H. Davis. *Process of extracting precious metals from their ores.*

A process for the extraction of the precious and other metals from ore, ore pulp, sands, slimes, tailings, mineral bearing earths

or other substances containing these metals, which consists in introducing chlorin gas into the ore and afterwards wholly or partially removing the excess of chlorin by forcing air into the material and afterwards treating with a cyanide solution to dissolve the chlorides.

694521—March 4, 1902. B. W. Begeer. *Cyanide process of extracting precious metals from ores.*

The process of treating material containing the precious metals, consisting in setting in motion in an endless path a solution of cyanide of potassium, introducing oxygen to the moving liquid, and finally subjecting the metal bearing material to the action of said solution.

696274—March 25, 1902. E. Schilz. *Cyanide process of extracting precious metals from their ores.*

An improved process in the art of extracting precious metals from their ores, said process consisting in thoroughly and intimately mixing peroxide of barium (BaO_2) with precious metal bearing material, and then subjecting the same to treatment with an alkaline cyanide solution.

701002—May 27, 1902. J. B. de Alzugaray. *Method of extracting precious metals from their ores.*

The process for treating ores containing precious metals and consisting in adding the crushed ore to a solution of sodium chloride, sodium carbonate, and potassium cyanide, then forcing through the mass a gaseous mixture of bromine and air and recovering the precious metals from the solution by any known means, such as electrolysis.

702305—June 10, 1902. E. D. Kendall. *Process of extracting precious metals from their ores.*

The process of treating ores carrying precious metals, which consists in treating such ore with a lixiviating solution, consisting of a cyanide, potassium percarbonate, and water, and finally extracting the precious metal from such lixivium.

705698—July 29, 1902. R. H. Officer, J. W. Neil, J. H. Burfeind, and F. H. Officer. *Cyanide process of working gold, silver, or other ores.*

The improvement in treating ores by the cyanide process, consisting in agitating the pulp containing the cyanide solution by a suitable gas under pressure, passing the gas and the hydrocyanic-acid gas liberated from the solution through a regenerating solution, and using the gas after passing through said regenerating solution to agitate a fresh quantity of pulp.

706303—August 5, 1902. L. B. Darling. *Process of extracting precious metals from ores.*

The process of extracting precious metals from finely divided materials or ores, which consists in spreading a comparatively thin layer of the material over a substantially flat and large working surface provided with drainage ducts or channels; then covering said material with suitable metal dissolving or cyanide solution; then passing a heavy roll back and forth over the charge of material, etc., thereby at the same time thoroughly agitating or stirring the charge and forcing some of the solution into the drainage ducts; then discharging said solution into the sump, and finally precipitating the precious metal from the solution.

707926—August 26, 1902. W. Hilt and C. E. Lane. *Process of extracting precious metals.*

The process of extracting precious metals from solutions thereof, which consists in producing cyanide solutions of said metals, vaporizing metallic zinc by means of heat, and conducting the vapor thus formed to a point beneath the surfaces of said solutions, thus producing finely divided zinc, which replaces the precious metals and thereby causes their precipitation.

708504—September 2, 1902. H. L. Sulman and H. F. Kirkpatrick-Picard. *Treatment of ore slimes.*

The process of treating ore slimes, which consists in separating, by means of a centrifugal machine, the ore slimes from the residual water with which they are mixed by adding a little lime to the charge, removing the bulk of the water, thereafter introducing into the machine an amount of leaching solution of a volume equal to that of the remaining quantity of adhering moisture and introduced into the slimes by centrifugal action, and replacing the moisture by the added leaching solution.

710496—October 7, 1902. S. T. Muffly. *Process of treating ores.*

The process of treating ores, which consists in injecting into said ores, as they are agitated and elevated and allowed to fall by gravity in a closed chamber, a chemical solution in the form of a spray, together with hot air under pressure, and allowing the elements and fumes freed by this operation to escape from said chamber.

718633—January 20, 1903. T. B. Joseph. *Gold extracting process.*

The process of extracting gold or silver from ore containing the same, when in a suitable condition, which consists in subjecting the said ore to the leaching action of a solution of water, cyanide of potassium, hydrate of calcium, and carbonic-acid gas, and introducing an oxidizing agent into the solution, and subsequently precipitating the gold from this solution.

719274—January 27, 1903. Z. B. Stuart. *Process of extracting metals from ores.*

The process of extracting precious metals from ore, consisting in agitating the pulp together with cyanide, water, and air by ebullition in one vessel, causing the mixture to assume an even consistency throughout, and passing the mixture through a mechanical agitator and combining therein a relatively smaller quantity of mixture with a relatively larger quantity of air and there forcing the pulp, cyanide, water, and air into intimate contact, and circulating the mixture through the two vessels.

722455—March 10, 1903. August Prister. *Process of precipitating gold from cyanide solutions.*

The process for the precipitation of gold or other precious metals from cyanide solutions, such as potassium cyanide, sodium cyanide, and bromine cyanide, which consists in acidifying the solution, adding a solution containing salts of mercury and copper, and then adding a solution containing zinc salts and a small percentage of a potassium ferrocyanide, or a small quantity of the cyanide solution discharged from the ordinary zinc-precipitation boxes.

722762—March 17, 1903. J. P. Schuch, Jr. *Process of separating precious metals from solvent solutions.*

The process of separating precious metals from their solvent solutions, which consists, first, in passing the solution through crushed limestone or phonolite to neutralize any free acid, then through zinc, wood ashes, asbestos wool or its equivalent, and charcoal or coke, to neutralize any free soda or carbonates, then through zinc shavings to precipitate the precious metals, then through charcoal to filter the solution and effect retention of a percentage of the precious metals, then through limestone or crushed phonolite to effect precipitation of zinc contained in the solution, and then alternately through zinc, charcoal, or coke and zinc to effect complete separation of the precious metals and thorough filtration of the solution.

725895—April 21, 1903. M. V. Uslar and G. Erlwein. *Process of extracting gold.*

The process for extracting gold from auriferous ores, which consists in lixiviating the ores with a solution of potassium cyanide, rhodanides, hyposulphites, and sodium chloride.

726294—April 28, 1903. F. J. Hoyt. *Method of extracting gold from ores.*

The method of milling gold ore, consisting of the following steps: First, pulverizing the ore; second, distributing the ore thinly over a wide, long, and open sluiceway; third, flowing the ore and propelling it forward over its bed by the action of a stream of chemical solution adapted to dissolve the ore; fourth, automatically screening and separating the solution from the tailings by the same force; and fifth, subjecting the solution to a reagent to precipitate the gold therein.

727659—May 12, 1903. F. W. Martino. *Method of extracting noble metals.*

The process of recovering gold from its cyanide solution, consisting in acidifying the solution and treating it at a raised temperature with barium-sulpho-carbide. The latter is manufactured by fusing two parts, by weight, of barium sulphate (baryta or heavy spar) $BaSO_4$ in an electric furnace with one part of carbon.

728397—May 19, 1903. T. B. Joseph. *Gold extracting process.*

The process of extracting gold and silver from ore containing the same when in a suitable condition, which consists in subjecting the said ore to the leaching action of a solution of water, cyanide of potassium, hydrate of calcium, peroxide of barium and carbonic acid gas, the ore being agitated by compressed air.

730835—June 9, 1903. D. Mosher. *Ammonia cyanide process of treating copper, nickel, or zinc ores containing precious metals.*

The process of treating refractory sulphur, tellurium, and arsenical ores containing copper, zinc, nickel, gold, and silver, consisting in first roasting such ores at a low red heat to transform the metals so transformable into sulphates, arsenates, or tellurates; then oxidizing reducing compounds by very dilute ammonia; and subsequently extracting the metals with an ammoniacal cyanide solution containing an excess of cupric oxide or hydroxide over and above that necessary to form metallic cyanide double salts.

731169—June 16, 1903. O. A. Ellis. *Apparatus for extracting metals from ores.*

An apparatus for extracting metals from ores, having in combination a receiving hopper having an inclined bottom, a discharge opening in said hopper, and inclined chute leading from said hopper and provided with a screen, a precipitating box connected with said inclined chute, means for causing a flow of chemical solution through said hopper, chute, and precipitating box and means for passing a current of electricity through said precipitating box.

731631—June 23, 1903. J. T. Terry, Jr. *Extracting gold or silver from slimes.*

An improvement in separating precious metals from slimes with which they are mixed, consisting in forming a solution with water, spraying said solution into tanks containing a cyanide solution made dense by the addition of salt, allowing the slime to settle through and into the solution, then drawing the clear liquor from the top through vertically disposed filters and discharging the sludge from the bottom into succeeding tanks containing a similar cyanide solution, allowing it to settle and again drawing off the clear liquor.

731839—June 23, 1903. G. A. Bahn. *Sulphuric acid process of extracting precious metals from solutions.*

The process of precipitating precious metals from solutions thereof, which consists in producing cyanide solutions of said precious metals, then acidulating with sulphuric acid said cyanide solutions, then immersing zinc in sheet, plate, or other form in the acidulated cyanide solution containing the precious metals; the chemical action thereupon taking place in the solution, dissolving zinc and precipitating the precious metals; then recovering from the precipitate of the preceding operation the precious metals by filtering and melting, or other process.

732605—June 30, 1903. G. E. Thede. *Process of leaching ores.*

The process of leaching ores which consists in mixing with the ore to be treated a cyanide solution, peroxide of hydrogen, and an oxide which is reducible by said peroxide of hydrogen.

732639—June 30, 1903. T. B. Joseph. *Gold extracting process.*

The process of extracting gold and silver from ore containing the same, when in a suitable condition, which consists in subjecting said ore to the leaching action of a solution containing water, cyanide of potassium, bromine, hydrate of calcium, peroxide of barium, and carbon dioxide, said carbon dioxide being forced into the leaching solution simultaneously with compressed air.

738758—September 15, 1903. J. B. de Alzugaray. *Extraction of precious metals from their ores.*

The process for extracting precious metals from their ores, consisting in first moistening the crushed ore with an alkaline solution and afterwards agitating it in a solvent solution and blowing through it an oxidizing agent composed of gaseous bromine and its acid and oxyacid compounds dissolved in air and finally recovering the metals from the solvent in any well-known manner.

745490—December 1, 1903. T. J. Grier. *Process of extracting precious metals.*

The process of extracting precious metals from slimes, consisting in directing the slimes into a settling tank, drawing off the thicker portions of the slimes and depositing the same into a leaching vat, of introducing a cyanide solution under pressure through perforations in the false bottom of the vat, causing the watery portions of the slimes to be displaced by said cyanide solution, then treating the charge with an air under pressure, and afterwards introducing through the false bottom of the vat a salt solution of greater density than the cyanide solution to displace the latter.

745828—December 1, 1903. E. B. Hack. *Process of extracting metals from ores.*

A cyanide process, consisting of the following steps in the order named: caking the pulp by pressure under conditions allowing the moisture to escape; introducing a weak solution of the solvent simultaneously with the introduction of air under pressure; drying the pulp by passing air under pressure therethrough; introducing a stronger solution of the solvent simultaneously with the introduction of air under pressure; and finally drying the cake by air pressure.

755951—March 29, 1904. J. Smith. *Process of treating ores.*

In the cyanide treatment of ores, the method of rendering insoluble in the cyanide solution ferrous oxide contained in a mass of moist crushed ore, which method consists in applying heat to said mass in the presence of air, previous to its treatment by the cyanide solution.

CLASS 204—ELECTROLYSIS.

Subclass 15—Aqueous Bath, Ores.

61866—February 5, 1867. J. H. Rae. *Improved mode of treating auriferous and argentiferous ores.*

This invention consists in treating auriferous and argentiferous ores with a current of electricity or galvanism for the purpose of separating the precious metals from the gangue. In connection with the electric current suitable liquids or chemical preparations, such, for instance, as cyanide of potassium, are used, in such a manner that by the combined action of the electricity and of the chemicals, the metal contained in the ore is first reduced to a state of solution and afterwards collected and deposited in a pure state.

Among the claims is one for the use of the platinum agitator as an electrode.

62776—March 12, 1867. J. H. Rae. *Improved mode of collecting gold and silver from sweepings, washings, etc.*

This invention consists in treating sweepings, filings, and washings containing gold or silver with a current of electricity or galvanism for the purpose of separating the precious metals from the impurities of foreign matter mixed with them. In connection with the electric current suitable liquids or chemical preparations, such, for instance, as cyanide of potassium, are used in such a manner that by the combined action of the electricity and chemicals the precious metals contained in the sweepings, filings, and washings are first reduced to a state of solution, and afterwards collected and deposited either as oxides or in a metallic state, and the operation of extracting or separating said precious metals from the sweepings, filings, or washings is attended with very little trouble and expense. During this operation the bath which contains the washings, filings, or sweepings acts as an electrode, and also as an agitator; and the third claim of the patent covers the use of this carbon electrode as an agitator.

90565—May 25, 1869. W. J. Lynd. *Improved process of separating iron and other metals from potters' clay.*

The process of removing iron, copper, and other discoloring matters from potters' clay and other argillaceous substances by subjecting the clay, when in solution, to the action of one or more magnets, or by passing through the bath containing such solution a current of electricity.

239300—March 22, 1881. A. Ryder. *Apparatus for treating ores.*

The invention has reference to apparatus for reducing ores in which the ore, while in a heated state, is dumped suddenly into a liquid or chemical solution for the purpose of disintegrating the ore and separating the particles preparatory to amalgamation. And the inventor claims, in an apparatus for disintegrating ores preparatory to amalgamation, the insulated vessel or nonconductor of electricity, provided with a metallic or plated hopper, in combination with an electrical generator or battery and conducting wire or wires.

246201—August 23, 1881. E. Reynier. *Electro-chemical treatment of ores.*

The method of treating ores of zinc and lead for the production of electricity and recovery of the metals by acting upon said ores in a voltaic couple with an electrolytic liquid having caustic alkali as the base, and precipitating the metallic oxides from said liquid.

272391—February 13, 1883. A. Thiollier. *Process of and apparatus for extracting metals from their ores.*

In combination with an electro-generator, a receptacle for conductively prepared ore or other material containing metal to be recovered, having attachments for the negative and positive polar conductors of the electro-generator, arranged, as described, in electrical communication with the mass of conductive ore by means of the electrolytic solution, whereby reduction is effected when the current is passed.

286208—October 9, 1883. L. Létrange. *Process of and apparatus for reducing zinc ores.*

The process of reducing zinc ores and producing pure metallic zinc and sulphuric acid simultaneously therefrom, which consists in simultaneously roasting sulphuret ores and carbonate ores in the same or communicating chambers, and thereby converting both ores into soluble sulphates, then leaching these roasted ores, and then depositing the metallic zinc from a solution of the sulphates by electric currents on metallic plates, and drawing sulphuric acid at the same time from the solution as fast as set free by the said electric currents; and the apparatus for use in the process of reducing zinc ores, which consists, essentially, in a reservoir for the sulphate solution; a precipitating vessel provided with suitable anodes and cathodes; a pipe provided with a regulating cock, leading from the reservoir to near the bottom of the precipitating vessel, and an outlet pipe for the freed acid, arranged in the said vessel at the desired level of the liquid therein, whereby the strength and quantity of the sulphate solution in the precipitating vessel are maintained constant.

291670—January 8, 1884. M. Body. *Process of and apparatus for obtaining gold and silver from their ores by combined electrolytic and amalgamating processes.*

The method of first subjecting gold and silver ores to the action of ferric salts, in combination with the electrolytic process, and the subsequent amalgamation of the metals with mercury under the continued action of the electric current; and the apparatus for effecting this process.

300950—June 24, 1884. H. R. Cassel. *Process of and apparatus for the separation of metals from ores and alloys.*

The process of separating metals from ores or alloys, especially those of an auriferous character, which consists in charging the ore or alloy in a powdered condition into an anode compartment, which is separated from the cathode compartment by porous material, said anode compartment containing a solution yielding nascent chlorine under the action of an electric current, and agitating said powdered material within said solution during the passage of the electric current; and the combination in an apparatus for treating ores and metals by electrolysis, of a cathode compartment, a negative pole therein, a rotary drum constituting the anode compartment, provided with porous material separating it from the cathode compartment, and with a series of carbon rods or plates arranged within the same, and suitable electric connections.

300951—June 24, 1884. H. R. Cassel. *Process of chloridizing ores by electrolysis.*

In the process of extracting gold from rebellious or refractory gold ores, the steps which consist in subjecting the ore to the action of a solution yielding nascent chlorine under electrolytic decomposition, and adding lime or its equivalent, whereby acids formed by secondary action during said decomposition are neutralized.

317245—May 5, 1885. E. P. Thompson. *Apparatus for the separation of gold from its ores by electro-chlorination and deposition.*

The combination, with an electrolytic cell for separating chlorine from its compounds and its anode, of a battery, a cathode consisting of a pipe through which steam is admitted to the cell for the purpose of increasing the rapidity of the separating, and conductors respectively connecting the same anode and cathode with the poles of said battery.

317246—May 5, 1885. E. P. Thompson. *Apparatus for the electro-deposition of gold from its chlorides.*

The combination, in an electrolytic cell, of an anode formed of a series of carbon rods set in a metal ring, and a cathode formed by two thin corrugated copper plates connected electrically, which are set, respectively, within and without the circle of carbons.

332705—December 22, 1885. H. H. Eames. *Apparatus for chloridizing gold, silver, and other ores.*

This invention consists of an iron vessel cylindrical in shape, lined with wood, having a cast iron cover, adjusted so as to be steam and vapor tight. It is also arranged with a set of stirrers, to which motion is communicated by crown and pinion wheels. It is also fitted with pipes, by means of which steam can be forced through the contents and held there under pressure. It is also furnished with two electrodes, by which electricity can be passed through the ore and chemicals operated upon, while the pressure is applied. The electric current is best obtained from a dynamo machine of ordinary construction used in the deposition of metals.

333815—January 5, 1886. M. Body. *Process of obtaining gold, silver, copper, nickel, and cobalt from their ores by electrolytic action.*

The process of separating gold, silver, copper, and other metals from chlorinated or chlorine containing ores by electrolytic action, consisting in first roasting the ores or subjecting them to an equivalent oxidizing treatment, as specified, and then subjecting the ore to the action of ferric-salt solutions, and at the same time passing an electric current through said solution, whereby the metal becomes dissolved and precipitated, and chlorine gas is generated at the positive pole, which reconverts the resulting ferrous salts into ferric salts.

351576—October 26, 1886. H. R. Cassel. *Process of extracting gold, etc., from ores.*

The process of separating metals from ores or alloys, especially those of an auriferous character, which consists in charging the ore or alloy in a powdered condition into an anode compartment, which is separated from the cathode compartment by a porous partition composed of asbestos, which permits the passage of the current with the metals in solution, and retains the ores within the anode compartment, said anode compartment containing a chloride solution, agitating and subjecting the charge to nascent chlorine produced from said solution during the passage of the electric current, passing the solution of metals through the asbestos partition, and depositing the metals in solution at the cathode.

357659—February 15, 1887. D. G. Fitzgerald. *Obtaining chlorine by electrolysis.*

The electro-chemical generation of chlorine by means of an anode of peroxide of lead in the form of dense, highly conductive layers, plates, or masses of any required form preferably obtained by the means hereinbefore described, the said anode being employed in conjunction with any suitable cathode and with an electrolyte capable of evolving chlorine.

360852—April 12, 1887. H. R. Cassel. *Apparatus for separating metals from ores or alloys.*

In an apparatus for separating metals from ores or alloys by electrolysis the combination of a journaled drum provided with carbon anodes, a hollow metallic shaft insulated on its exterior and extending through said drum, said shaft being perforated within the drum and separated from the interior thereof by a filter, and a screw conveyor within said hollow shaft.

360853—April 12, 1887. H. R. Cassel. *Apparatus for separating metals from ores or alloys.*

In an apparatus for separating metals from ores or alloys by electrolysis the combination of a rotary drum constituting the anode compartment and having a suitable electric connection, a rotary cathode compartment having a suitable electric connection and provided with an automatic valve, a porous diaphragm separating said anode and cathode compartments, a fixed bracket, and an arch shaped arm attached to said bracket in the path of said valve for opening of the latter.

362022—April 26, 1887. H. Liepmann. *Apparatus for separating metals from ores or alloys by electrolysis.*

In an apparatus for separating metals from ores or alloys by electrolysis the combination of an anode compartment, a cathode compartment, a filtering diaphragm separating said compartments, a dense porous diaphragm for separating said compartments during one step of the operation, and mechanism whereby the dense porous diaphragm may be placed in apposition with or removed from the opening between the anode and cathode compartments.

379764—March 20, 1888. C. F. Croselmire. *Wet process of extracting pure zinc from its ores.*

The process which consists in immersing roasted zinc ore in dilute acid, passing an air blast through the solution until the impurities are oxidized, and finally drawing off the zinc solution and depositing or precipitating the zinc.

387036—July 31, 1888. C. P. Bellows. *Process of cleansing gold and silver where mechanically coated in ores with refractory substances.*

The process of cleansing refractory ores prior to the recovery of the precious metals therefrom, which consists in immersing said ores in a solution of a sodium chloride and caustic soda, heating said solution, and at the same time subjecting the ores to the action of the electric current, whereby the ore is rendered free milling.

391360—October 16, 1888. H. H. Eames. *Apparatus for chloridizing ores.*

In a device for chloridizing metallic ores, the combination of a hermetically sealed tank, metallic plates placed inside the said tank and mounted upon insulated supports, whereby they will be insulated from each other and from the tank, the said plates forming the two elements of a galvanic battery, a stirrer placed in the said tank and between the said plates a solution containing the ore to be treated, by which a galvanic current will be excited between the said charging steam in the said tank, whereby the said solution will be heated and a pressure maintained in said tank.

399209—March 5, 1889. J. H. Rae. *Electric amalgamator.*

In an apparatus for working ores, a pan or tub with an internal copper ring and rotating arms or stirrers, in combination with a horizontal wooden ring suspended above the tub, a copper plate forming the upper surface of said ring and perforated to admit carbons which pass loosely through the plates, said carbons having heads or transverse pins at the upper ends, and the movable elastic plates or springs pressing upon the heads of the carbons to hold them in contact with the copper plate.

407386—July 23, 1889. J. C. Wiswell. *Bath or solution for separating metals from their ores.*

The process of producing a bath or solution for the separation of metals from their ores, consisting in subjecting a solution of salt water, muriate of ammonia, and muriatic acid to a current of electricity, then placing this solution in a tank containing liquid mercury, and subjecting the whole to a current of electricity, said mercury serving as the anode.

410228—September 3, 1889. J. C. Wiswell. *Solution for use in separating metals from their ores.*

A solution or bath for use in separating metals from their ores, consisting of chlorine in solution, sodium chloride, ammonium chloride, hydrochloric acid, and bichloride of mercury.

415576—November 19, 1889. W. von Siemens. *Process of electro-deposition of metals.*

The process which consists in lixiviating ore in separate vessels with a solution containing ferric sulphate, passing the resulting ferrous sulphate successively through a series of compartments containing cathode plates, and in which cells the solution is subjected to the action of an electrical current by which the metal in solution is deposited, then passing the remaining liquid successively through a second series of compartments containing anode plates of insoluble material and separated from the first-mentioned compartments by nonmetallic diaphragms, whereby the ferrous sulphate is oxidized and reconverted into ferric sulphate, which solution is again used to lixiviate ores.

418134—December 24, 1889. H. F. Julian. *Process of extracting gold and silver from their ores.*

The improvement in the process of extracting gold and silver from ores, which consists in agitating the pulverized ore in closed vats with chlorine, bromine, or iodine and water under pressure of a fluid forced into the vat, and after the gold and silver have combined with the halogen, adding mercury and again agitating under pressure of a fluid forced into the vat, next passing the ore, mercury, and solution over amalgamated copper surfaces forming the cathode of an electric circuit, and subsequently submitting the mixture to electrolytic action between cathodes of mercury below and suitable anodes above.

452125—May 12, 1891. W. von Siemens. *Apparatus for extracting metals from their ores.*

The combination of a trough for the flow of liquid, composed of numerous sections connected at alternate ends, with an inlet at one end and an outlet at the other, with two longitudinal shafts in each section of the said trough, said shaft carrying beaters and being entirely immersed in the liquid contained in the trough, and a heating pipe located below and between the said shafts.

459023—September 8, 1891. C. Schreiber and H. Knutsen. *Process of extracting antimony from ores.*

In the extraction of antimony from ore, the process which consists in subjecting the crushed ore to the action of a solution of sulphide of sodium and then precipitating the antimony in metallic form by electrolysis, adding hydroxide of sodium to the solution.

460354—September 29, 1891. W. von Siemens. *Apparatus for electrolytically separating metals from ores.*

In an electrolytical cell, the combination of a revolving cathode, a trough shaped anode situated below the said cathode, in the trough of which the cathode revolves, a screen permitting the passage of the electrolyte and of electricity and capable of preventing the passage of vibrations of the electrolyte situated between the said cathode and anode, and means for supplying the electrolyte above the screen and for withdrawing the oxidized liquid from the bottom of the trough of the anode.

473105—April 19, 1892. G. J. Atkins. *Electrolytic apparatus for separating gold and other metals from their ores.*

Electrolytic apparatus for separating gold and other metals from their ores, which consists of an upright anode compartment through which the ore is passed continuously, having within it an anode constructed to receive and retard the descent of the ore, while the ore itself forms a more or less soluble portion of such anode pole, and an upright cathode compartment and pole, the said anode and cathode compartments communicating through an opening closed by a porous diaphragm and having outlets at their lower ends for the removal of the ore which has been acted upon in the anode compartment and of the metals and other substances that have been deposited or precipitated in the cathode compartment.

484869—October 25, 1892. G. J. Atkins. *Process of separating gold and other metals from their ores.*

The continuous process of separating gold and other metals from their ores, which consists in passing such ore through the anode compartment of an electrolytic apparatus in contact with the anode and retarding the descent of the ore in the said anode compartment while such ore is kept in contact with the anode pole of such compartment, so as to form a more or less soluble portion of such anode pole, and then subjecting the ore to the process of amalgamation.

495212—April 11, 1893. J. F. Wiswell. *Process of, and apparatus for, treating ores.*

An improved process of treating ores which consists in submerging mercury in a solution of common salt connecting the mercury with the positive pole of a generator and the salt solution with the other pole, so that the current will decompose the salt solution and cause the chlorine to be attracted to the mercury forming calomel; treating the calomel with aqua regia forming a soluble mercuric chloride, diluting the latter with water, treating undecomposed salt solution with an electric current to produce sodium hypochlorite and introducing the soluble mercuric chloride and sodium hypochlorite simultaneously upon the crushed ore.

495637—April 18, 1893. J. Pfleger. *Process of extracting zinc by electrolysis.*

The process of obtaining zinc by electrolysis out of a zinc containing anode, which consists in adding to the bath a basic zinc-salt solution adapted to act as electrolyte, to which basic zinc-salt solution a conducting neutral salt has been added.

495715—April 18, 1893. S. R. Whitall. *Process of lixiviating ores.*

The process of separating gold and silver from their ores, which consists, first, in roasting the ore to oxidize the base metals; and, secondly, in subjecting the roasted ore to the action of a solution of potassium cyanide and sodium hyposulphite, and subsequently precipitating the dissolved metals; and the process of separating gold and silver from siliceous ores, which consists in subjecting the ore admixed with caustic soda and potash to the action of a solution of potassium cyanide and sodium hyposulphite.

497014—May 9, 1893. F. W. Cleghorn. *Process of separating precious metals from ores.*

The process of separating gold and silver from ores, consisting in filtering through the ores a solution of sulphuric acid and salt, and precipitating the gold and silver in the filtrate solution by placing metallic iron in the filtrate and passing an electric current through the filtrate.

501997—July 25, 1893. S. H. Emmens. *Apparatus for the electrolytic extraction of metals.*

In apparatus for the electrolytic extraction of metals, a vat having an anode lining on its floor and sides, in combination with a suitable cathode or cathodes suspended within the vat and a nonporous and nonconducting inner wall or curb located between the side linings and the cathode or cathodes and extending from the upper surface of the floor lining to above the surface of the electrolyte, and serving to support a lining of the substance to be acted upon in contact with the anode side linings and to prevent short-circuiting between said anode side linings and the cathodes.

507130—October 24, 1893. C. Hoepfner. *Electrolytic production of metals.*

The process of obtaining copper and silver free from other metals, which consists in forming a cuprous chloride solution of these metals by leaching a cupriferous and argentiferous material with a cupric chloride solution containing a solvent for cuprous chloride, separating from the cuprous chloride solution so obtained such metals as arsenic, antimony, cobalt, and the like, extracting the silver by precipitation, electrolyzing the cuprous chloride solution, preventing the solution at the anode from commingling with the solution at the cathode, mixing together the two solutions after having been acted upon by the electric current and preventing an accumulation of iron therein by oxidizing and removing the latter.

512361—January 9, 1894. P. C. Choate. *Art of producing metallic zinc.*

The method of producing from an impure solution of zinc salts a zinc electrolyte free from depositable impurities, which consists in subjecting the solution to the action of an electric current to precipitate and deposit the depositable impurities, and at the same time preventing the re-solution of such impurities in the solution by neutralizing the acid set free in the bath with a neutralizing agent which is free from any depositable impurities soluble in the solvent element of the bath.

512362—January 9, 1894. P. C. Choate. *Process of preparing solutions carrying salts of zinc.*

The process of forming a solution carrying salts of zinc, which consists in forming a sulphate solution of the soluble elements of the ore and recovering the same therefrom by evaporation and crystallization, heating the crystallized product to drive off the salts of metals more volatile than zinc and convert those less volatile than zinc into compounds insoluble in water and finally treating the mass with water to dissolve the zinc element.

518732—April 24, 1894. P. C. Choate. *Art of producing metallic zinc.*

The process of continuously producing metallic zinc by electrolysis, which consists in depositing the zinc from an acidulated solution of a zinc salt, drawing off from the bath the free acid liberated therein, dissolving in such acid oxidized zinc, in the state of fume,

freed from its more volatile soluble impurities, and returning the solution thus formed to the bath from time to time, as required, to maintain the electrolyte.

526099—September 18, 1894. P. Danckwardt. *Apparatus for and process of extracting gold or silver from ores.*

The process of extracting gold and silver from ores, which consists in subjecting the same simultaneously to the action of cyanide of potassium, an alkali sulphide, and to electrolysis; and the combination of a main apparatus consisting of a revolving outer drum having blades, an insulated inner drum and electric connections, with an auxiliary apparatus consisting of a series of communicating tanks, rotating insulated drums and electric connections.

528023—October 23, 1894. L. Pelatan and F. Clerici. *Extracting gold from its ore.*

The combination with a crushing mechanism and an amalgamator, of a series of vessels containing a solution of cyanide of potassium and a salt of sodium, each vessel having an amalgamated copper bottom connected to one pole of a generator of electricity and a central shaft having a zinc pipe and agitator connected to the other pole, a filter, a series of communicating closed vessels of lead, each containing a body of aluminum chips resting on a perforated diaphragm above the inlet and rising nearly to the outlet, and means for creating a vacuum beneath the filter to drive the fluid through and into the series of lead vessels under pressure.

531169—December 18, 1894. V. Engelhardt. *Process of extracting metals from sulphide ores, etc.*

The process of treating the sulphur compounds of metals, which compounds have combined therewith other ore compounds not soluble in a solution of an alkaline sulph-hydrate, which consists in extracting the sulphur compounds by treatment with an alkaline sulph-hydrate, thereby also generating sulphureted hydrogen, subjecting the solution thus formed to the action of an electric current in the cathode compartment of an electrolytic cell, in the anode compartment of which is an alkaline chloride, thereby obtaining the metals, reforming the sulph-hydrate, and liberating free chlorine, treating the ore residues, resulting from the sulph-hydrate bath with such chlorine, and subjecting the solution thus obtained to the action of the sulphureted hydrogen first generated in the sulph-hydrate bath.

537423—April 9, 1895. F. H. Long and D. C. Skaden. *Apparatus for recovering precious metals from their ores.*

An apparatus for recovering precious metals comprising a revoluble drum, a perforated metal tube opening from said drum and provided with a fabric jacket, a series of plates secured to the inner surface of the drum and having inwardly extending blades or flanges electric connections to the plates and tube for rendering the same of opposite polarity, a rotatable conveyor located and working in said tube and a fixed vent pipe passing axially through the drum head and opening into the interior of the drum near the top thereof.

538522—April 30, 1895. E. D. Kendall. *Process of and reagent for recovering silver and gold from solutions.*

The process of the recovery of gold and silver from solutions, which consists of the following steps: (first) the subjecting of the ore containing the precious metals to the action of a solvent, thus obtaining an aqueous solution of the solvent and the minerals contained in the ore; (second) subjecting the said solution to the electro-chemical action of a mercurial amalgam; (third) subjecting the valuable precipitate secured by the preceding process to the action of dilute acid in the presence of carbon; (fourth) the recovery of the valuable metal from the result of the preceding process.

543546—July 30, 1895. E. J. Fraser. *Process of and apparatus for treatment of precious metals.*

The process of separating gold or other precious metal held in an electrolytic solution, which consists in passing the solution through a vessel containing alternating porous layers of zinc and carbon, to set up a local voltaic action which tends to decompose the solution, precipitating the gold in the carbon by filtration.

543673—July 30, 1895. M. Crawford. *Process of extracting precious metals from their ores.*

The improved process of removing precious metals from their ores which consists, first, in lixiviating the ore with a cyanide solution which has been subjected to the action of an anode separated from its corresponding cathode by a porous partition which substantially prevents the circulation of the electrolyte; second, in withdrawing said solution and removing the precious metals therefrom; third, in again subjecting the solution to the action of an anode separated from its corresponding cathode as before and using it over again in continuous rotation.

543674—July 30, 1895. M. Crawford. *Process of extracting precious metals from their ores.*

The improved process of extracting precious metals from their ores, which consists in forming a solution of a cyanide and a cyanate of the corresponding base, the total amount of cyanate being not less than 25 per cent of the total amount of cyanide present; lixiviating the ore therewith and extracting the dissolved precious metals from said solution.

543675—July 30, 1895. M. Crawford. *Apparatus for extracting precious metals from their ores.*

An apparatus for extracting precious metals from their ores, which consists in the combination of a tank wherein the solvent liquid is stored; a revoluble lixiviating receptacle; a pipe running from said storage tank to the lixiviating receptacle; an amalgamating table; means for causing the lixiviating receptacle to discharge its contents continuously upon the amalgamating table; a separating tank; means for conducting ore which has passed over the amalgamating table into the separating tank; means for separating the solid contents of this separating tank from its liquid contents; a third tank; connections whereby the solvent liquid thus separated is passed to said third tank; means for reclaiming the precious metals from the solution in said third tank; and connections whereby the solvent liquid is run from the third tank to the storage tank; and a separator for removing the tailings of the ores of precious metals from their accompanying solvent solution, which consists in the combination of a tank into which the ores and solution are discharged; a conveyer running from the bottom of said tank to a point exterior thereto by which the solids are separated from the liquids; a car filter with a permeable bottom situated below the discharge end of the conveyor; and a second tank below said car filter.

544610—August 13, 1895. E. W. Clark. *Process of and apparatus for extracting ores by electrolysis.*

In an electric chlorinator for gold ores, the combination of the hollow cylinder constructed in longitudinal sections united by bands, and having the series of separate boxes or chambers communicating with its interior; the electrical connections consisting of the anode in the cylinder chamber, and the cathodes in the boxes or amalgamating chambers, the agitator shaft provided with the spirally arranged series of stirrer arms and adapted to revolve in the cylinder chamber, and the stuffing boxes at the ends of the cylinder.

546873—September 24, 1895. E. A. Ashcroft. *Process of treating zinc-bearing ores.*

In the treatment of zinc bearing ores and zinc bearing products, the method of simultaneously depositing zinc from a catholyte free from iron, and raising a ferrous salt solution to the ferric state, which consists in passing the zinc bearing solution free from iron, around the metallic cathodes of an electrolytic apparatus, and simultaneously passing the ferrous salt solution around the insoluble anodes of the said electrolytic apparatus.

549907—November 19, 1895. A. L. Eltonhead. *Apparatus for extracting gold.*

In an apparatus for extracting gold and other metals, the combination of a mercury receiving box, a horizontally movable vessel therein, having its lower end open and unobstructed whereby mercury placed within the box may, in seeking its level, enter said vessel, a horizontally placed anode strip suspended within the latter, means for adjusting the strip vertically, a cathode connection and conductor wires adapted to connect the anode and cathode with a suitable dynamo or battery.

551648—December 17, 1895. L. Pelatan and F. Clerici. *Electrolytic process of obtaining precious metals.*

In an apparatus for the extraction of precious metals by direct electrolytic action, the combination with an electrolytic vat having cathodes arranged at its bottom, of anode cylinders arranged above the said cathodes, anode plates alternating with said cylinders, a generator of electricity having its poles connected to said anode cylinders and plates and to the cathodes, means for rotating the anode cylinders which are provided with agitators, a force pump having injection pipes to discharge beneath the anode plates and cylinders, said pipes being provided at or near their mouths with interior, concentric rods having spiral ribs, or feathers, and suction pipes having their open ends arranged above the anode plates.

552960—January 14, 1896. C. Hoepfner. *Process of producing cuprous oxides.*

The process which consists in leaching cupriferous materials with a cupric chloride solution containing calcium chloride, whereby a solution containing cuprous chloride is obtained, converting the cuprous chloride in a portion of the solution into cupric chloride by means of a suitable acid as sulphurous acid in the presence of oxygen, freeing the other portion of the solution from metals other than copper, and converting the cuprous chloride therein into cuprous oxide by means of a suitable reagent, as caustic lime.

553816—January 28, 1896. L. Pelatan and F. Clerici. *Process of and apparatus for extracting gold from its ores.*

A single continuous process for the extraction of precious metals from their ores, and the amalgamation of the same, which consists in treating said ores with a comparatively weak solution of a soluble cyanide, such as cyanide of potassium, adding thereto a peroxide such as hydrogen binoxide, increasing the electric conductivity of said solution by adding chloride of sodium, increasing the solvent power of said solution by passing a relatively weak current of electricity through the same, retaining the sodium chloride in the solution practically without decomposition and continuously revolving the anode in the solution over a fixed cathode of mercury.

556092—March 10, 1896. O. Frölich. *Process of extracting noble metals from ores.*

The process of extracting precious metals from a lye containing also inferior metals, said lye containing substantially five grains of each of the said metals to the pint, which consists in subjecting the said lye to the action of an electric current of substantially twelve amperes for each two square yards of cathode surface, whereby the gold is separated by electrolysis.

563143—June 30, 1896. J. Douglas. *Process of extracting copper from ores.*

The method of extracting copper from solid cuprous chloride, which consists in moistening said solid cuprous chloride with water, inserting both electrodes of an electric circuit in the said solid cuprous chloride, and then passing an electric current therethrough.

563144—June 30, 1896. J. Douglas. *Process of extracting copper from ores.*

The process of extracting copper from the solid cuprous chloride, which consists in suspending the said solid cuprous chloride in an acidulated electrolyte, inserting the cathode of an electric circuit into the solid cuprous chloride, and the anode into the electrolyte, and passing an electric current therethrough.

566894—September 1, 1896. P. Danckwardt. *Apparatus for extracting gold and silver from ore.*

The combination of a revolving barrel having an amalgamated copper lining with nonconducting bottoms, a series of inclined perforated metal strips secured to such bottoms, insulating rings that sustain the bodies of such strips, and with electric connections that communicate with the barrel and the strips.

566986—September 1, 1896. R. Keck. *Cyanide process of extracting precious metals from their ores.*

The process of extracting precious metals from their ores, which consists in dissolving said metals in a cyanide solution and extracting them therefrom by electrolytic precipitation effected by alternating plates of lead and aluminum, the former being anodes and the latter cathodes.

567503—September 8, 1896. L. Pelatan and F. Clerici. *Process of extracting gold and silver from their ores.*

The process, which consists in submitting the ores of gold and silver to the action of a comparatively weak cyanide solution containing chloride of sodium, intensifying the solvent power of the solution by the passage of a continuous electric current having an electro-motive force below that required for the decomposition of sodium chloride, and continuously revolving the anode from which the current is supplied to the solution over a mercury cathode.

568099—September 22, 1896. L. Pelatan and F. Clerici. *Electrolytic apparatus for extracting gold and silver from their ores.*

The combination with a vat having a flat bottom, of a cathode of mercury spread thereon, an anode having the form of an endless belt, rolls arranged near the ends of the vat to support and give continuous movement to said anode in parallelism with the surface of the cathode, and means for imparting continuous movement to said anode, in one direction, it being provided with stirring devices moving with it.

568724—October 6, 1896. E. Andreoli. *Apparatus for electro-deposition of gold or silver.*

In an apparatus for the electro-deposition of gold and silver from a solution, a tank provided with one or more anodes and a series of amalgamated cathodes, each cathode consisting of perforated, skeleton, or network plates and a layer of mercury in the bottom of the tank into which each of the cathodes dips, said layer of mercury being connected with the negative pole of electricity, thereby constituting a common vehicle for the current from all the cathodes while at the same time maintaining the said cathodes constantly amalgamated.

568741—October 6, 1896. H. R. Cassel. *Process of extracting gold from substances containing it.*

The process of extracting gold from ores, which consists in decomposing a bromide of an alkaline base by electrolysis, dissolving the gold by the anode solution, adding the cathode solution, running the product through a mixture of iron and carbon to precipitate the gold, and redecomposing the liberated bromine solution by electrolysis.

568843—October 6, 1896. V. Engelhardt and A. Nettel. *Process of treating metallic sulphides.*

The process of treating a metallic sulphur compound, which consists in first converting the said compound into a soluble double sulphide by treating it with any suitable reagent, such as the sulph-hydrate of calcium in aqueous solution; then decomposing the resulting solution by electrolysis to produce the metal and sulphureted-hydrogen gas, then treating the spent solution with carbonic acid gas to precipitate a carbonate of the base and liberate sulphureted-hydrogen gas, then recovering the oxide of the

reagent and the carbonic-acid gas from the precipitate by calcination, then combining the sulphureted-hydrogen gas given off during the process with the said oxide to form more reagent, and using the recovered carbonic-acid gas to treat more spent solution.

571468—November 17, 1896. T. P. Barbour. *Process of treating ores.*

The process of treating ores, which consists in first treating the raw material with copper oxide and sulphuric acid, then chlorinating the pulp thus treated, introducing the chlorinated mass into a suitable agitator having zinc therein, and establishing an electric current through the mass in the presence of zinc; and a chlorinating tank for treating ores consisting of a revoluble cask having a single manhole and a circular series of bungholes, copper pole disks secured within the cask at opposite ends thereof and arranged in an electric circuit, insulator bracing posts arranged between said disks and the outer heads of the tank, flanged guide rings encircling said cask at an intermediate point, spurrings encircling the cask near its opposite ends, and a horizontal drive shaft carrying guide rolls engaging said flanged guide rings and drive pinions engaging said spur rings.

573233—December 15, 1896. M. Netto. *Process of precipitating precious metals from their alkali cyanide solutions.*

The process of precipitating silver and gold from their alkali cyanide solutions, which consists in acidulating the alkali cyanide solution containing said metals with hydrochloric acid so as to precipitate silver chloride, separating said silver chloride by filtration, subjecting the acid filtrate to the action of the electric current so as to deposit the gold on the cathode, and regenerating the cyanide solution by the addition of caustic alkali.

578171—March 2, 1897. C. P. Turner. *Electrolytical apparatus.*

An electrolytic apparatus, provided with an anode consisting of a nonconducting receptacle coated with an anticorrosive substance and provided with an outer coating of a conducting material and means for connecting said outer coating with the positive pole of a source of electrical supply.

579872—March 30, 1897. J. H. Haycraft. *Process of treating auriferous and argentiferous ores.*

The process of treating ores consisting in introducing the ore into a pan, adding thereto mercury and soluble salts capable of yielding chlorine by electrolysis, raising the ore contents of the pan to about the boiling point of water and passing a current of electricity through the heated mass while stirring the same to secure a simultaneous electrolytic chlorination and electro-amalgamation, and maintaining the anode out of vertical alignment with the mercury cathode.

581160—April 20, 1897. H. Hirsching. *Process of treating ores containing silver and gold.*

The process of treating ores, which consists in subjecting them in the presence of moisture to the action of ammonia and a nitrate, and then precipitating the metal or metals from the resulting solution.

582077—May 4, 1897. E. Motz. *Apparatus for extracting precious metals.*

In an apparatus for extracting precious metals, the combination of a rotative drum provided with a manhole and having a valved connection for the admission of compressed air, a core of insulating material mounted to turn in the said drum, metal plates forming the positive and negative electrodes of an electric circuit and arranged respectively on the drum and core, and an electrical connection for said plates on the core, the said connection being arranged to lock the drum and core together.

584242—June 8, 1897. P. G. Salom. *Process of making commercial lead from lead ore.*

The process of converting lead ore into commercial lead, without the application of heat, by subjecting the ore to the action of nascent hydrogen, electrolytically developed, producing thereby a spongy mass, and afterward, while the mass is in a nonoxidized condition, applying a consolidating pressure.

585355—June 29, 1897. C. A. Burghardt and G. Rigg. *Process of obtaining metallic zinc and copper from ores.*

The improved process of recovering metallic zinc and metallic copper from cuprous zinc ore, which consists in treating the roasted and ground ores with an ammoniacal solution, then in freeing the resultant liquid from iron dissolved by said solution, then in depositing the metallic copper on suitable metallic plates acting as a couple, and in finally effecting the electrolytic deposition of the metallic zinc.

585492—June 29, 1897. J. F. Webb. *Method of an apparatus for separating precious metals from their solvent solutions.*

The improved method of separating precious metals from a solvent solution containing the same, consisting in passing the solution alternately through a body of carbon and zinc, and subjecting the same in its passage to an air current; and a metallurgical filter for this purpose containing the same, consisting of a series of alternate compartments, or receptacles, containing, respectively, carbon and zinc, through which the solvent solution is passed with an upward and downward flow, and electric circuit completing connection between the zinc and carbon.

588076—August 10, 1897. B. Mohr. *Process of treating sulphide ore.*

The process for treating sulphide ore by acting on the pulverized ore with acid sodium or potassium sulphate, so as to obtain a solution of sulphate of zinc, depositing the zinc by electrolysis and thus recovering the acid alkali sulphate, and treating the insoluble residue obtained by the lixiviation for recovery of the other metals.

588740—August 24, 1897. B. Becker. *Apparatus for treating gold and silver ores.*

In apparatus for the treatment of gold and silver ores the combination of a vat provided with amalgamating plates and adapted to contain cyanide of potassium, in solution, and the ore to be treated, a vat containing the electrodes of an electrolytic apparatus and means for causing the circulation of the cyanide of potassium solution through the amalgamating vat, and for distributing it in the electrolytic vat.

590801—September 28, 1897. W. L. Brown. *Process of treating rebellious ores.*

The process of treating ores finely divided and mixed with water, which consists in adding a suitable compound to said ores and water, which compound contains an element which has a chemical affinity for the base constituents of the ore, then passing an electric current through said material to unite the said element chemically with the base constituents and to liberate the precious metals, then circulating the material over an amalgamated surface which is not in the electrical circuit, and finally returning the material again through the field of electrolytic action.

592055—October 19, 1897. E. C. Ketchum. *Process of treating ores.*

The process of treating mixed sulphide ores containing lead and zinc, which consists in first roasting the ores, then subjecting the roasted ores to the action of a solution of caustic alkali in the presence of heat to remove from the ores the lead and the zinc, then subjecting the caustic solution containing the lead and zinc to electrolytic action in one or more cells to remove the lead, the anodes of which cells are immersed in a volume of pure caustic solution, which is separated by a porous medium from the electrolyte containing the lead and zinc, and then subjecting the caustic solution or electrolyte containing the zinc only to electrolytic action in one or more cells to remove the zinc.

592973—November 2, 1897. E. Motz. *Electrolytic apparatus.*

In an electrolytic apparatus the combination with a frame or sluice of a series of convex cathode plates located in the bottom of said frame or sluice, a series of anode plates having curved under faces and disposed above said cathode plates, blocks secured to the

anode plates and supported in the frame or sluice, each block having a recess in its upper edge, a series of conductors connected with said anode plates and terminating in said recesses in the blocks, a conducting rod disposed in said recesses on the first-mentioned conductors and having a notch therein, a crossbar passing through said notch, a conductor with which said crossbar is electrically connected, locking devices for securing the crossbar to the frame or sluice, and a conductor connected with the cathode plates.

594611—November 30, 1897. S. H. Emmens. *Process of and apparatus for removing zinc from zinciferous ores.*

The process of treating zinciferous ores, which consists in pulverizing and roasting the ore, leaching it in a series of vessels through which the solution flows continuously, and subjecting the contents of each vessel intermittently to electrolytic action, whereby the solution is rendered alternately acid and neutral or more acid and less acid in contact with each body of ore; and an apparatus for treating zinciferous ores, comprising a series of leaching vats, each provided with an inlet pipe extending to the bottom and with an exit pipe or trough leading from the top of the vat, and each provided at bottom with an insoluble anode, a series of movable cathodes suspended above said vats, means for raising and lowering the cathodes of adjoining vats alternately, and an electric circuit to the respective poles with which said anodes and cathodes are connected.

597820—January 25, 1898. N. S. Keith. *Art of obtaining gold and silver from auriferous and argentiferous materials.*

The process of obtaining a precious metal from its ores, which consists first in dissolving the gold or silver in a cyanide solution containing cyanide of mercury and free cyanide of an alkaline metal, such as cyanide of potassium, and then passing a current of electricity through said solution to a metallic cathode, whereby an easily removable layer of the precious metal and mercury is simultaneously deposited upon said cathode.

598193—February 1, 1898. E. Andreoli. *Apparatus for electro-deposition of gold and silver.*

In apparatus for the electro-deposition of gold, silver, or other metals, anodes of peroxidized lead acting in the presence of and in combination with a cyanide or cyanide-compound solution.

600351—March 8, 1898. E. A. Ashcroft. *Treatment of metalliferous ores and products.*

The improved process of preparing a solution suitable for leaching zinc bearing ores of zinc bearing products, consisting in electrolyzing a zinc bearing solution successively in contact with a suitable cathode and an anode resulting from the preliminary furnace treatment of products or ores containing copper and iron, and then depositing the copper from the resulting ferrous solution, and simultaneously raising the iron content of such solution to the ferric state by electrolyzing the said resulting ferrous solution successively in contact with suitable cathodes and insoluble anodes.

601068—March 22, 1898. F. W. Whitridge. *Method of and apparatus for extracting gold from its ores.*

The method of extracting gold from a weak cyanide solution, which consists in circulating the solution over anodes of iron and cathodes of lead, said cathodes being formed of thin plates arranged at short distances apart and having from 9 to 10 square meters of surface for each ton of solution in contact with them; and subjecting the said solution while in motion to an electric current of from 3.5 to 4 volts, and of from 0.5 to 1.5 amperes per square meter of cathode surface; and in apparatus for obtaining gold from a weak cyanide solution by electrolysis, the combination with a cell provided with anodes of iron and cathodes of lead formed of thin plates, said cathode plates having from 9 to 10 square meters of surface to each ton of solution in the cell; of means for circulating the solution in the cell, and means for subjecting the solution to a weak current of electricity.

603904—May 10, 1898. J. R. Hebaus. *Apparatus for extracting precious metals.*

An apparatus for extracting precious metals from their ores, comprising a tank having an amalgamated copper lining forming a cathode and a multiplicity of agitators, each rotating on its own axis and at the same time traveling around the tank, the said agitators forming an anode and an electric circuit.

605835—June 21, 1898. E. and G. Andreoli. *Electrolytic production of amalgams, etc.*

An apparatus for the production of amalgam, consisting of a cell provided with positive and negative compartments separated by porous diaphragms, the negative compartments having a raised middle portion in the form of a table or block between the sides of which and the said partitions are narrow vertical spaces, the top of the block or table and the vertical spaces being covered and filled with a continuous body of mercury forming a cathode.

614572—November 22, 1898. J. C. McNulty. *Method of and apparatus for treating ores.*

The art of extracting precious metals from their ores, consisting in mixing pulverized ore with an electrolytic fluid, causing the mixture to flow from one level to another between adjacent electrode plates of opposite polarity, passing an electric current between said plates and vibrating the electrodes in a direction substantially at right angles to the plane of said electrodes for the purpose of preventing the polarization thereof; and in apparatus for the electrolytic treatment of ores the combination of a plurality of vats arranged in pairs communicating at the top, adjacent electrode plates of opposite polarity suspended within said vats and connected with a source of electricity, vibratory supports for said electrodes, means for vibrating the same at substantially right angles to their planes, a pressure conduit for pulp leading to the bottom of the first vat to provide an upward current therethrough, and an exit at the bottom of the succeeding vat providing a discharge for the downward current of pulp overflowing from the top of the vat preceding.

616891—January 3, 1899. G. D. Burton. *Electrolytic apparatus for treating metals and ores.*

In an electrolytic ore treating apparatus, the combination of a tank for containing an electrolyte, an anode disposed in said tank, a cathode disposed in said tank, a screen or deflector also disposed in said tank between the anode and cathode and adapted to distribute the ore or material being treated, said screen having a conductive surface connected to the negative pole of an electric source whereby it is adapted to collect a portion of the product reduced from the ore by the action of the current and the electrolyte.

617911—January 17, 1899. E. A. Smith and M. H. Lyng. *Method of extracting metallic ores.*

The wet process of extracting copper from its ores having precious metal therein, which consists in digesting the pulverized ore under action of heat and an oxidizing agent, in presence of sulphuric acid, exposing the dissolved sulphates to metallic copper for precipitation of the silver, treating the filtrate electrolytically to deposit the copper, evaporating the lean electrolyte to concentrate the free acid, and crystallize the metallic sulphates, and finally calcining such crystallized sulphates to properly regenerate them as oxidizing agents for reuse.

623822—April 25, 1899. L. Pelatan. *Apparatus for treating ores or the like.*

In apparatus, the combination with a circular vat, of a revolving anode, situated above and parallel to a mercury cathode, with an unobstructed space above the surface of the cathode, the said anode having arms which extend close to the peripheral wall of the vat and are suspended from a shaft, and are provided with pins or stirrers projecting upward and downward to within a short distance of the underlying cathode, and projections or baffles extending inwardly from the inner surface of the peripheral wall of the vat.

626972—June 13, 1899. T. Craney. *Electrolytic apparatus for deposition of metals from solution.*

In an electrolytic apparatus, the combination of an outer tank provided with suitable feed and discharge connections for the liquid into the bottom and top, respectively, and an electrolytic couple, composed of sheet or analogous electrodes each folded in a fabric, with oppositely projecting marginal portions and rolled together into a tight bundle and sealed in the tank, whereby the fabric inclosing the electrode forms a porous medium through which the electrode is compelled to flow.

627442—June 20, 1899. L. Pelatan. *Process of electrolytically treating ores.*

The improvement in processes of treating ores electrolytically, consisting in adding to a sludge, consisting of ore and water, a solvent and picric acid as an oxidizing agent and then passing an electric current therethrough.

631040—August 15, 1899. J. E. Greenawalt. *Process of extracting precious metals from their ores.*

A process for the treatment of gold and silver ores which consists, first, in properly roasting the pulverized ore; second, placing the ore in a filtering vat; third, washing the ore to remove soluble salts; fourth, in passing through the ore an electrolyzed solution consisting of a solution of chlorides—chiefly sodium and ferric chlorides—with a small percentage of bromides and small quantities of chlorine, bromine, and hypochlorous acid, with such other compounds as result from the electrolysis of a chloride and bromide solution; fifth, passing the solution after it leaves the ore through a precipitating tank; sixth, passing the solution after it leaves the precipitating tank through the positive or anode compartment of an electrolytic cell, keeping the solution separate and distinct from the solution in the negative or cathode compartment of the cell; and, seventh, returning the solution from the regenerating cell to the ore in the vat and passing it thence to the precipitating tank, again to the regenerating cell, and again to the ore as often as may be required to effect the necessary saving of the values.

633544—September 19, 1899. H. S. Badger. *Electrolytic apparatus for precipitating metals.*

A precipitating tank comprising the tank body, having a mercury coated surface in its bottom, a revoluble shaft suspended in the tank and provided with hollow arms having perforations on their lower sides to deliver air or vapor in proximity to the said surface, means for rotating the revoluble devices, means for introducing air or vapor to the hollow arms, and an electric circuit in which the shaft, agitating arms, and mercury coated surface are located.

639766—December 26, 1899. L. E. Porter. *Apparatus for extracting precious metals from ores.*

The combination of a rotatable barrel adapted to form the cathode; a porous lining of nonconducting material arranged inside the barrel; a lining of filtering material arranged inside the nonconducting lining; anode plates arranged inside the filter lining; a source of electrical energy, having one pole connected with the barrel and the other pole connected with the anode plates.

640718—January 2, 1900. C. P. Tatro and G. Delius. *Process of extracting precious metals.*

In the process of separating precious metals from ores, the steps comprising electrolytically depositing a portion of the precious metals in the bath upon a drum cathode revolving partially immersed in the bath, at the same time scraping the said deposit from the drum, also simultaneously depositing other portions of similar precious metals in the same bath upon a cathode of sodium amalgam.

641571—January 16, 1900. W. Witter. *Process of producing solution of cyanogen halide.*

The process for producing a solution of cyanogen halide by electrolyzing in a bath without a diaphragm and with inert electrodes a solution containing an alkali cyanide, an alkali halide, and the salt of a metal which forms an insoluble hydroxide.

649151—May 8, 1900. W. Wright. *Apparatus for extracting metals from refractory ores.*

An apparatus for extracting metals from refractory ores, comprising a tank for receiving a sludge of such ores; a stationary, horizontal, perforated partition in said tank, forming beneath it a chamber; a cathode on the bottom of the tank within said chamber; a filtering medium carried on the partition; a number of pins arranged in a series of concentric circles projecting upward from said partition; a main driving shaft; a series of radial arms supported by said shaft, and a plurality of anodes carried by said arms and working between the series of concentric pins.

650646—May 29, 1900. F. H. Long. *Apparatus for electrolytic reduction of ores.*

An electrolytic apparatus, the combination with a reducer vessel; its bottom cathode and a diaphragm above said cathode, of a set of dependent anodes, each consisting of a carbon head; a copper stem extended therefrom through the vessel; an incasing iron tube carried by the vessel head to sustain the anode pole; a vulcanite sheath for said tube, and suitable elastic gaskets to expansively close the joints.

653538—July 10, 1900. N. L. Turner. *Electrolytic apparatus.*

An electrolytical apparatus, comprising a tank, rotary agitators located therein eccentrically, a series of electrodes whose main portion is concentric with the tank, while the portions adjacent to the agitators are curved concentrically with the axes of said agitators, and electrodes of opposite polarity to those first named.

654437—July 24, 1900. W. A. Caldecott. *Method of extracting gold from cyanide solutions containing the precious metals.*

Means for extracting gold from cyanide solutions in depositing cells, consisting in a mechanical mixture of zinc shavings and lead shavings.

656305—August 21, 1900. W. Strzoda. *Process of electrolytically extracting zinc from ores.*

The process of electrolytically extracting zinc from its ores, which consists in placing the disintegrated or pulverized ore in its natural state in an electrolytic vat containing an aqueous alkali-metal solution capable of dissolving the ore, with production of a zincate and in direct contact with the cathode, and closing the circuit through the vat, thereby precipitating zinc and the alkali metal at the cathode, the alkali metal reacting with the water to regenerate the solvent solution.

657032—August 28, 1900. A. M. Rouse. *Apparatus for electrolyzing ores.*

In an apparatus of the class described having an anode and a cathode suitably arranged therein, the combination of a tank having an outer compartment, a tube located therein having an open upper end and provided at its lower end with openings forming communication from said compartment, a driving shaft projecting within said tube, an inner cup carried by said shaft, wings carried by said cup, an outer cup carried by said wings, a discharge duct, and a valve arranged to close said duct.

662286—November 20, 1900. E. Motz. *Electrolytic apparatus.*

In an electrolytic cell having open ends, the combination with a removable crossbar and means for supporting it in position, of a metallic plate covering the bottom and two sides of the bar, and forming the anode plate of the cell, of a metallic plate arranged horizontally below and parallel with the bottom of the crossbar, so as to form a passage between such plate and the bottom of the crossbar, such plate forming a cathode plate of the cell, and an auxiliary metallic cathode plate arranged vertically and parallel with the sides of the crossbar and in circuit with the horizontal cathode plate, such vertically arranged plate extending below the plane of the bottom of the crossbar, so as to more or less obstruct the said passage.

664537—December 25, 1900. J. Douglas. *Process of extracting copper.*

The process of reducing copper ore and matte, which consists in electrolyzing solid cuprous chloride, employing the gases evolved in the treatment of copper ore and matte, employing the electrolyte resulting from the electrolyzing of the solid cuprous chloride as a solvent for the cuprous chloride so produced, and recovering the copper from the solution by electrolysis.

668842—February 26, 1901. A. M. Rouse. *Apparatus for electrolytically extracting and depositing gold and silver from their ores.*

In an apparatus, the combination of a series of pulp receiving tubs, anodes and cathodes arranged in said tubs, an agitation tube having communication with said tubs at their upper and lower ends, an agitator arranged in said tube, perforated conduits located in the upper ends of said tubs, chutes located beneath said conduits onto which the ore pulp is discharged, and deflectors located beside said conduits adapted to direct the flow of pulp onto said chutes as it passes through said conduits.

669752—March 12, 1901. P. W. Knauf. *Electrolytic apparatus.*

An element for an electrolytic series, consisting of a metallic receptacle having its lower portion of less diameter than the upper portion and having a bottom surface which is inclined upward radially from the center to the outer periphery, in combination with an exterior peripheral seat arranged below the upper edge, and an orifice adjacent to said seat.

669926—March 12, 1901. C. Hoepfner. *Process of electrolytical extraction of metals.*

A process which consists in placing a soluble metallic anode in a solution capable of dissolving the same, placing a suitable cathode in a second similar solution containing a metal more electro-positive than that of the anode, interposing a third similar solution of less solution pressure between the two first mentioned, placing an auxiliary cathode therein, separating the solutions by suitable diaphragms, maintaining the solutions in motion and at a temperature above normal, passing a current, thereby dissolving the anode and precipitating the cathode metal at the cathode, and part of the diffused anode metal at the auxiliary cathode, precipitating the anode metal from the anode and intermediate solutions and returning the resulting solution when enriched in cathode metal to the cathode cell.

678526—July 16, 1901. C. P. Stewart. *Apparatus for the recovery of gold from cyanide solutions.*

An apparatus for recovering precious metals from flowing cyanide solutions, comprising in combination a relatively long substantially horizontal trough, means for supplying the solution at one end thereof, a partition near the receiving end of the trough for distributing the solution, a retaining partition at the discharge end of the trough adapted to retain the solution in the trough to the desired height, a body of quicksilver in the bottom of the trough between said partitions, a series of transverse anode supports extending substantially from partition to partition, a series of anodes adjustably mounted in said supports and extending down into the path of the flowing solution, and suitable electric connections.

682155—September 3, 1901. C. P. Tatro and G. Delius. *Electrolytic apparatus for extracting precious metals.*

In apparatus for extracting precious metals, a tub; a mercurial cathode in the bottom thereof, a principal anode, means for lowering it into and raising it out of the tub, and a minor anode permanently in the tub.

689018—December 17, 1901. W. Orr. *Method of recovering cyanides.*

The method of regenerating cyanide solutions which have become fouled by the presence of zinc and copper contained in the solutions, as double cyanide of zinc and copper with the alkaline metals which consists, first, in passing through the solution from a series of zinc anodes to a corresponding series of metallic cathodes a current of electricity; next, in introducing into such solution alkaline hydrate, being hydrate of the monovalent alkali metals and hydrate of the divalent alkali metals in the proportion of about two to one; next introducing into the solution a soluble alkali-metal sulphide, and finally removing the resulting zinc-sulphide precipitate.

689674—December 24, 1901. A. I. Irwin. *Machine for extracting metal from ore.*

In a machine for the automatic and continuous extraction and deposition of metal from ores at one and the same time, a treatment tank, an endless anode traveling in said tank, the upper and lower stretches of the anode being in position to be immersed in the solution in the tank, diagonally disposed blocks of insulating material attached to said anode, cathodes in the tank, one under each stretch of the anode, and connections with a source of electricity.

689959—December 31, 1901. E. L. Graham. *Process of disintegrating and comminuting minerals or ores.*

The process of treating ores, consisting of the following steps: First, immersing the ores in a solution of sulphuric and hydrofluoric acids incapable of dissolving the ore; second, passing an electric current of sufficient strength to disintegrate the ore through the solution; and third, extracting the metal from the ore.

699964—May 13, 1902. F. H. Long. *Electrolytic converter.*

In electrolytic converters, the combination with the closed reducer vessel having the anode and cathode terminals and the interposed diaphragm dividing the vessel into upper anode and lower cathode chambers, of a combined separator and vent pipe connected to the cathode chamber beneath the diaphragm extending upwardly above the level of said diaphragm and having a free outlet for the gases.

700941—May 27, 1902. N. S. Keith. *Process of treating copper or other ores for obtaining their contents of metals.*

The process of electrolyzing a solution of a metal; to deposit the metal therefrom, which consists in passing it as an electrolyte through a succession of two or more electrolytic cells, arranged so that the cells are connected in electrical series with a source of electricity; the anodes insoluble, the electrodes of each cell in electrical multiple, and having gradually increasing surfaces, whereby there is a gradual reduction of the current density as the metal of the electrolyte is deposited.

704639—July 15, 1902. C. Hoepfner. *Leaching and extraction of metals from their ores.*

The process of extracting metals, which consists in leaching a suitable material containing copper, lead, and silver, with a warm cupric-chloride solution containing a solvent of cuprous chloride, in quantity less than is required for saturation, thereby dissolving lead and silver chlorides, precipitating them, reconverting the solution into cupric chloride, using the same for leaching fresh quantities of ore, leaching the residues with a similar hot solution more concentrated in cupric chloride, thereby dissolving copper and recovering those metals therefrom, reconverting the resulting solution into cupric chloride, and returning the latter into the cycle of operations.

706436—August 5, 1902. F. T. Mumford. *Apparatus for the electrolytical treatment of ores or slimes.*

An apparatus for the extraction of metals from their ores and slimes, comprising a rotatable cylindrical metallic drum, a copper lining therein, a body of mercury in the drum to maintain the lining amalgamated, a valve-controlled inlet and outlet, and a relief valve at one end, a plurality of conductive rods insulated from and passing longitudinally through the drum, a metallic ring connecting the bars, trailing electrical contact for the drum and one for said ring.

709817—September 23, 1902. C. E. Dolbear. *Electrolytically treating ores.*

The method of reducing metals from their ores, which consists in dissolving the crushed ore in a compound containing a nitric acid radical, adding to the mixture sulphuric acid, and subjecting the resultant compound to the action of an electric current.

725864—April 21, 1903. W. B. McPherson. *Apparatus for the treatment of gold or other ores.*

A precipitating apparatus for depositing gold and silver from a cyanide of potassium solution and from other chemical solutions, comprising a precipitating box having downward, inclined bottom with openings therein, valves located in said openings, said box provided with a series of electric conducting plates vertically arranged therein and connected with a source of electric supply, a gauge receptacle, a pipe communicating with said receptacle and with the precipitating box through which the said solution passes back and forth, a float within said receptacle and adapted to reciprocate therein, a yoke secured to said float, a horizontally reciprocating valve rod, devices for connecting said yoke with said valve rod, means for operating said valves in connection with valve rod, and means for conveying said solution from said precipitating box and returning the same thereto.

737554—August 25, 1903. L. P. Burrows. *Electrolytic apparatus.*

An electrolytic apparatus, comprising a dissolving vessel having a revoluble anode, a depositing vessel having a cathode, means for conveying an unbroken stream of liquid from the dissolving vessel, and an electric circuit including said anode and cathode, whereby the electric current is caused to traverse the stream of liquid flowing from the dissolving vessel into the depositing vessel.

741231—October 13, 1903. W. H. Davis. *Process of treating cyanide solutions.*

The process for treating cyanide solutions during or subsequently to their contact with the ore, consisting in introducing into the solution an alkaline hydrate and then subjecting the mixture to the action of an alternating electric current, thereby raising the osmotic pressure to dissociate the double salts in the solution, causing precipitation of the hydrates of the base metals and to combine the freed cyanogen with the alkaline hydrates to cause simultaneous regeneration of the cyanide in the solution and clarifying of the latter.

741439—October 13, 1903. C. E. Baker and A. W. Burwell. *Process of treating ores.*

The process of recovering copper and nickel from a solution of sulphates of copper, nickel, and iron, which consists of electro-depositing the copper, neutralizing the solution, and electro-depositing the nickel with a current density insufficient to deposit the iron.

743668—November 10, 1903. R. Suchy and H. Specketer. *Extracting chromium from chrome-iron ore.*

The process of making soluble chrome-iron ore and obtaining chromium compounds, which consists in heating the ore together with sulphuric acid in excess and an oxidizing agent and separating by filtration the precipitated insoluble ferrisulphate from the chromosulpho acid.

749843—January 19, 1904. H. R. Cassel. *Process of extracting precious metals by electrolysis.*

The process of extracting precious metals by electrolysis, which consists in circulating the pulp between vertical electrodes, amalgamating a vertical cathode, successively deflecting the rebounding mercury back upon said cathode, removing the amalgam, neutralizing the alkali in the mercury, and returning the mercury to the cathode.

749844—January 19, 1904. H. R. Cassel. *Apparatus for extracting precious metals by electrolysis.*

An apparatus for extracting precious metals by electrolysis, comprising a tank, inclosed vertical electrodes, mercury deflectors, and pulp guards at the sides of the cathode, an elevated pulp box, communicating perforated launders, means for lifting the pulp into said box, an elevated mercury pot, communicating slidable perforated troughs, and means for lifting the mercury into said pot.

755302—March 22, 1904. E. A. Le Sueur. *Extraction of copper from comminuted mineral mixtures.*

The method of obtaining metallic copper from mixtures containing it, which consists, first in treating said mixtures with an ammoniacal solution containing a cupric compound or compounds, so as to dissolve the desired copper, then in removing a portion of the total copper contents of the solution, and lastly in using the partially exhausted solution over again to dissolve fresh copper as before.

QUICKSILVER

QUICKSILVER.

By Joseph Struthers, Ph. D.

The production of quicksilver in the United States during 1902 was confined to the states of California and Texas. In 1889 production was reported only from California and Oregon. Table 1 shows the comparable items for the census years of 1902 and 1889.

Table 1.—*Comparative summary: 1902 and 1889.*

	1902	1889
Number of mines	41	17
Number of operators	37	11
Salaried officials, clerks, etc.:		
Number	117	20
Salaries	$154,154	$34,966
Wage-earners:		
Average number	1,329	961
Wages	$881,340	$591,323
Contract work	$23,164	(1)
Miscellaneous expenses	$59,767	$35,490
Cost of supplies and materials	$322,267	$219,622
Product:[2]		
Total value	$1,550,090	$1,190,500
Quicksilver—		
Quantity, flasks	34,291	26,464
Value	$1,467,848	[3]$1,190,500
Cinnabar—		
Quantity, short tons	11,727	2,750
Value	$82,242	(1)

[1] Not reported.
[2] The United States Geological Survey reports $1,467,848, which does not include 11,727 short tons of cinnabar, valued at $82,242, mined but not reduced.
[3] Exclusive of 20 flasks, valued at less than $1,000, produced in Oregon.

The quantity of quicksilver produced in 1902 showed an increase of 29.6 per cent over that reported at the Eleventh Census. There were 11,727 tons of cinnabar reported, valued at $82,242, which was not reduced. The amount of mechanical power decreased 17 per cent. The growth in the number of wage-earners and in the wages paid them appears to have been normal. The increase in the amounts expended for supplies and materials, and for miscellaneous expenses also, is a normal growth.

Idle mines reported for 1902 numbered 56—50 in California, 3 in Oregon, and 3 in Texas. There were 10 operative mines for which no production was reported, the employees being engaged in development work. Seven of these mines were located in California and 3 in Oregon. The statistics for these nonproductive mines are summarized in the following statement. Among the owners of the idle mines and those for which development work was reported, were 7 incorporated companies, with a total par value of stock issued amounting to $10,683,000.

Development work: 1902.

Number of mines	10
Number of operators	9
Salaried officials, clerks, etc.:	
Number	8
Salaries	$9,525
Wage-earners:	
Average number	35
Wages	$27,498
Contract work	$150
Miscellaneous expenses	$955
Cost of supplies and materials	$7,169

Capital stock of incorporated companies.—Table 2, which follows, shows that 21 operators, or 56.8 per cent of the total number, were incorporated companies, and gives their capitalization.

Table 2.—*Capitalization of incorporated companies: 1902.*

Number of incorporated companies	[1]21
Capital stock and bonds issued	$39,017,700
Capital stock:	
Total authorized—	
Number of shares	2,222,620
Par value	$44,100,000
Total issued—	
Number of shares	2,136,143
Par value	$38,872,700
Dividends paid	$171,994
Common—	
Authorized—	
Number of shares	2,179,620
Par value	$39,800,000
Issued—	
Number of shares	2,093,143
Par value	$34,572,700
Dividends paid	$150,494
Preferred—	
Authorized—	
Number of shares	43,000
Par value	$4,300,000
Issued—	
Number of shares	43,000
Par value	$4,300,000
Dividends paid	$21,500
Bonds:	
Authorized—	
Number	1,450
Par value	$145,000
Issued—	
Number	1,450
Par value	$145,000
Interest paid	$6,000
Assessments levied	$173,500

[1] Includes 18 in California and 3 in Texas.

The par value of capital stock, common and preferred, and of bonds issued, amounted to $39,017,700. This seems excessive for an industry producing a product valued at only $1,550,090. The dividends paid on the stock were small, amounting to $150,494 on the common and $21,500 on the preferred. The interest paid on bonds was $6,000. The dividends paid on the common stock amounted to four-tenths of 1 per cent of the par value of all common stock issued. The dividend on the preferred stock was five-tenths of 1 per cent on the total amount issued.

Employees and wages.—The average number of wage-earners employed each month, as given in Table 8, was remarkably uniform, varying only from 1,303 in July and August to 1,358 in November, a difference of 55. In this respect the industry presents a uniform operation, due to the fact that the demand for cinnabar and mercury is steady, and that the mines reported were located in California and Texas, where the climate permits of uninterrupted working. Child labor is relatively unimportant, amounting to about one-half of 1 per cent of the whole number of wage-earners.

The daily rates of pay at which the workmen engaged in the various occupations were employed are also given in Table 8. Miners constituted 46.2 per cent of the total number of wage-earners, and of all miners 75.4 per cent were employed at rates not less than $1.75 per diem. Of the 38 engineers reported, all received $2 or more per diem, and the same is true of 35 out of the total of 42 firemen. Miners' helpers formed an important class, constituting 17 per cent of the total number of wage-earners. These workmen had various duties and their rates of pay ranged from 75 cents to $2.99 per diem. The timbermen and track layers received good wages, 11 receiving from $2 to $2.24, and 7 from $3 to $3.24 per day. The class "all other wage-earners" is chiefly composed of ordinary laborers. Of these workmen 43.7 per cent received less than $2 per diem, while 56.3 per cent received $2 or more.

Mechanical power.—Primary power aggregating 1,808 horsepower was reported. This was applied chiefly through steam engines, of which there were 56 reported, or an average horsepower of 28. Over 8 per cent of the total power was furnished by 17 gas or gasoline engines. Three water wheels were reported, representing 22 horsepower. Sixty horsepower was supplied by 5 air compressors. There were also 3 electric motors with 15 horsepower.

Production in the United States.—The quicksilver produced in the United States during 1902 amounted to 34,291 flasks of 76.5 pounds each, aggregating 1,189.9 metric tons, and valued at $1,467,848, as compared with 26,464 flasks, 918.3 metric tons, valued at $1,190,500 in 1889. This shows an increase in quantity of 7,827 flasks, and in value of $277,348, over the statistics at the Eleventh Census.

Mercury is transported in cylindrical wrought iron flasks, each 5 inches in diameter and about 14 inches long, closed with a screw plug, and having a capacity in the United States of 76.5 pounds. At Almaden, Spain, and Idria, Austria, the capacity is slightly less, being 76 pounds.

Of the 34,291 flasks produced in the United States during 1902, California contributed 28,972 flasks, or 84.5 per cent, and Texas 5,319 flasks, or 15.5 per cent. Except as noted below, the entire output of quicksilver in the United States has been derived from California, and statistics of production and the average value per flask for that state during the period from 1889 to 1902, inclusive, are given in Table 3, as reported by the United States Geological Survey. In addition to the output of California, the following quantities have been produced in Texas and Oregon: Texas, in 1899, 261 flasks; in 1900, 750 flasks; in 1901, 2,932 flasks; and in 1902, 5,319 flasks; Oregon, in 1900, 233 flasks and in 1901, 75 flasks.

TABLE 3.—*Production of quicksilver in California and the average price per flask at San Francisco: 1889 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

YEAR.	Quantity (flasks each containing 76.5 pounds).	Average price per flask.
1889	26,464	$45.00
1890	22,926	52.50
1891	22,904	45.25
1892	27,993	40.71
1893[1]	30,164	36.75
1894	30,416	30.70
1895	36,067	37.04
1896	30,765	34.96
1897	26,691	37.28
1898	31,092	38.23
1899	29,454	47.70
1900	26,317	44.94
1901	26,720	48.46
1902	28,972	43.20

[1] Beginning with 1893, figures taken from Annual Statistical Bulletin of the California State Mining Bureau.

Prices.—The price of quicksilver in the United States is affected by several conditions, chiefly the quantity available and the mode of disposition of the product, whether for home consumption or for export. In the latter case a relatively low price is obtained for the metal, as it has to compete in foreign markets with the European product. In some cases the prices vary according to the rates of transportation from the various entry ports to the points of consumption, in order to compete with the European product which may enter at other ports; thus, comparatively higher export prices are obtained at western coast ports of Mexico than at interior points of consumption adjacent to railroads leading to eastern ports.

The average monthly price of quicksilver, per flask, during 1902, as reported by the United States Geological Survey, is given in Table 4. The lower averages during 1902 indicate the periods of largest sales for export, and the higher averages indicate periods of sales for domestic consumption.

TABLE 4.—*Average monthly price of quicksilver per flask at San Francisco during 1902.*

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

MONTH.	Price.	MONTH.	Price.
January	$45.30	August	$42.71
February	44.29	September	42.35
March	45.56	October	42.37
April	45.00	November	42.64
May	44.83	December	45.00
June	45.77		
July	43.39	Average	44.10

The average monthly price of quicksilver, per flask, at New York during 1902 was $48.37 for January, and $48 for the other months of the year.

Imports and exports.—The quantity of quicksilver imported during the past decade has been inconsiderable, owing to the fact that in this period approximately one-half of the domestic product has been exported. For the past five years the quantities imported have been merely nominal.

Table 5, published by the United States Geological Survey from statistics of the United States Treasury Department, shows the quantity and value of the annual imports of quicksilver from 1889 to 1902, inclusive, and Table 6, from the same source, shows the quantity and value of the exports of quicksilver during the period 1889 to 1902, inclusive. Prior to 1901 very nearly the entire quantity of quicksilver exported was shipped from San Francisco, but in that year only 5,479 flasks of the total of 11,219 flasks exported were shipped from that port, practically the entire exportation being consigned to Mexico and Central America.

TABLE 5.—*Quicksilver imported and entered for consumption in the United States: 1889 to 1902.*

[1] Mexico exported 324 tons of quicksilver in 1899, 335 tons in 1900, and 335 tons in 1901.
[2] Statistics not yet available.

A detailed summary showing the statistics for quicksilver during 1902 is given in Table 8.

DESCRIPTIVE.[1]

Historical.—Mercury or quicksilver has been known to mankind from very early times. No mention of it appears, however, in the books of Moses or in the works of the early Greek writers. The earliest known reference is in the writings of Theophrastus (300 B. C.), who speaks of liquid silver or quicksilver. Dioscorides refers to artificial mercury as ὑδράργυρος, water silver; Pliny gave it the name of *hydrargyrum* in contradistinction to native mercury, which he called *argentum vivum*. The name quicksilver was undoubtedly suggested by the liquid form and silver color of the metal, while that of mercury was derived from the name of the Greek god Mercury, probably in allusion to the quickness and ease with which it flows in any direction. The salts of mercury also were known at a very remote period. The early Arabians were familiar with mercurous chloride (Hg_2Cl_2), or calomel, and mercuric oxide (HgO), the red oxide, and the alchemists possessed a knowledge of mercuric chloride ($HgCl_2$), corrosive sublimate. The mineral cinnabar, mercuric sulphide, has been used as a pigment from the most ancient times on account of its enduring vivid red color. By reason of its peculiar physical properties in being liquid, very heavy, and not acted on by air, sulphuric acid, or hydrochloric acid, mercury perhaps more than any other metal has excited the attention and curiosity of experimenters.

Physical and chemical characteristics.[2]—The symbol of mercury (Hg) is derived from the old Latin name *hydrargyrum*. Its atomic weight is 199.8. Aside from bromine, mercury is the only elementary metal which exists in a liquid form at ordinary tempera-

[1] In this paper the older term "quicksilver" has been retained for use in connection with the description of the mining and metallurgy of the metal, as it is the name generally accepted by the public. The modern name "mercury" has been reserved for the description of the physical and chemical properties of the metal.
[2] Inorganic Chemistry, Newth, page 554 ff.

tures. It is a bright tin-white liquid, and, when free from impurities, the globules retain a perfectly spherical shape. The luster is mirror like, and like that of silver it is preserved in air free of sulphurous gases. Mercury, when cooled to a temperature of $-38.8°$ C., is transformed into a tin-white, ductile, malleable mass, softer than lead and crystallizing in octahedrons. During the cooling it contracts uniformly until the temperature of solidification is reached, at which point a considerable contraction takes place, and, as a consequence, the solidified mercury will sink below the surface of liquid mercury. At 0° C. the specific gravity of mercury is 13.596 and at $-38.8°$ C. the specific gravity of solidified mercury is 14.193. In very thin films the liquid metal is transparent and of a violet-blue color when viewed by transmitted light.

The specific heat of solidified mercury (between $-78°$ C. and $-40°$ C.) is 0.0247; that of liquid mercury (between 0° C. and 100° C.) is 0.0333. Its thermal conductivity is 667, compared with that of silver taken at 1,000, and its electrical conductivity at 22.8° C. is 1.63, silver at 0° C. being taken at 100.

The boiling point of mercury at the standard pressure of 760 mm. is 357.25° C. Above this temperature it becomes a transparent, colorless vapor, having a density of between 6.7 and 7.03, referred to air as a unit. The density of gaseous mercury compared with hydrogen is 100.92, and as its atomic weight is 199.8, this element in a gaseous form consists of monatomic molecules. Mercury gives off vapors at all temperatures. This may be illustrated by suspending a piece of gold leaf above the surface of mercury in a stoppered bottle; the gold leaf will slowly assume a white color from the formation of gold amalgam on the surface.

In its liquid and gaseous forms mercury is poisonous, producing salivation when taken either internally through the lungs or stomach or by absorption through the pores of the skin. Mercury is not tarnished by exposure to the air, nor is it acted on by many gases; hence it is an invaluable aid to the chemist in the collection and measurement of gases which are soluble in or absorb water. When subjected to prolonged heating in the air, mercury is slowly transformed into red mercuric oxide (HgO), which at a higher temperature is again decomposed into its elements—mercury and oxygen.

Liquid mercury is converted by agitation with oil or by trituration with sugar, chalk, or lard into a dull-gray powder. This process is called "deadening," and is used to prepare mercurial ointment, the gray powder consisting simply of very finely divided mercury in the form of minute globules.

Mercury is not attacked by hydrochloric acid. Concentrated sulphuric acid has no action on it in the cold, but rapidly dissolves it when heated, yielding sulphur dioxide gas. Diluted nitric acid dissolves it slowly when cold, forming mercurous nitrate, and concentrated nitric acid attacks it rapidly, forming mercuric nitrate and fumes of oxides of nitrogen.

In commerce mercury is usually contaminated with a small proportion of dissolved metals, which cause a globule to lose its spherical shape and drag a tail behind it while flowing over an inclined surface. If the mercury is shaken in the air, these metallic impurities become oxidized and form a black powder or scum, which incloses small drops of the metal, thus preventing them from coalescing. Mercury in this condition is said to be "floured." Commercial mercury is best purified by distillation, but for ordinary purposes the impurities may be removed almost entirely by repeated agitation with dilute nitric acid or perchlorate of iron, either of which attacks the impurities and forms with them soluble nitrates and chlorides, respectively, which are removable by washing with water.

Occurrence.—Mercury is found in nature chiefly as the ore cinnabar, mercuric sulphide (HgS or Hg_2S_2). It occurs also, though less commonly, as native mercury, which is disseminated in many cinnabar deposits in the form of fine globules, sometimes in large quantities. From a commercial standpoint, cinnabar and metallic mercury are the only ores of importance.

The following is a list of all the known ores of mercury, classified according to composition:

List of the mercury ores.

CLASS.	Mineral name.	Composition.
Native mercury	Native mercury	Hg.
Amalgams (silver)	Amalgam	AgHg or Ag_3Hg_3.
	Arquerite	$Ag_{12}Hg$.
	Kongsbergite	$Ag_{36}Hg$.
Amalgams (gold)	Gold amalgam	$(AuAg)_5Hg_5$.
Sulphides	Cinnabar	HgS or Hg_2S_2.
	Metacinnabarite	HgS or Hg_3S_3.
	Hepatic cinnabar or "liver ore."	HgS or Hg_2S_2, with carbon and clay.
	Livingstonite	HgS_2 Sb_2S_3.
	Ammiolite	HgSb CuS and Fe.
	Barcenite	HgSb S and Fe.
Sulpho-selenides	Onofrite	Hg(S, Se).
	Guadalcazarite	Hg(S, Se).
	Leviglianite	Hg(S, Se) with Fe.
Selenides	Tiemannite	HgSe.
	Lehrbachite	(HgPb) Se.
Tellurides	Coloradoite	HgTe.
	Magnolite	Hg_2Te O_4.
Chloride	Calomel	Hg_2Cl_2.
Oxychlorides	Terlinguaite	Hg_2ClO.
	Eglestonite	$Hg_6Cl_4O_2$.
Iodides	Coccinite	HgI.
	Tocornalite	(HgAg) I.
Oxide	Montroydite	HgO.

Important compounds of mercury.—With most metals mercury forms a series of alloys called amalgams; in some cases, as with the alkali metals, the formation of the alloy is attended with a rise of temperature, while in other cases, as with tin, an absorption of heat results. Sodium and potassium amalgams are decomposed by contact with water, yielding hydrogen gas and an alkaline hydroxide; for this reason sodium amalgam is used in the laboratory as a reducing agent. Zinc amalgam is acted upon very slowly by dilute sulphuric acid, and on this account the surface of zinc plates in galvanic batteries is usually amalgamated. Tin amalgam is used to produce the reflecting surface of ordinary mirrors, and amalgams of gold, copper, and zinc are used in dentistry as fillings for teeth.

In addition to the amalgams, mercury forms the fol-

lowing commercially important compounds: With chlorine, mercurous chloride (HgCl), or calomel, largely used in medicine, and mercuric chloride ($HgCl_2$), or corrosive sublimate, used in medicine, and in surgery as an antiseptic, and also in the preparation of anatomical specimens, and in the dressing of furs and skins; with oxygen, mercurous oxide (Hg_2O), the suboxide or gray oxide of mercury which is of little importance commercially, and mercuric oxide (HgO), the red oxide of mercury or red precipitate, used in medicine and for various purposes in chemical analyses; with sulphur, cinnabar, mercuric sulphide (HgS), or vermilion, the same as cinnabar, the chief ore of mercury. Vermilion is invaluable as a pigment, because of the permanence of its vivid cochineal-red color. It is made artificially in two ways—one, termed the dry method, in which an intimate mixture of metallic mercury and sulphur in proper proportions is heated in a retort and the sublimed product condensed and ground very fine, the beauty of the tint depending largely upon the fineness of the material; and the other, called the wet method, by which various compounds of mercury are transformed into the sulphide by the use of chemical reagents. Vermilion prepared by the wet method is of better quality than that made by the dry process. The manufacture of vermilion has declined in recent years on account of the competition of cheaper pigments which have supplanted its use. The most important of these is "orange mineral" (red lead), which is toned up to the proper color by the use of eosin, one of the aniline dyes. These imitation vermilions are now employed for almost all of the more common uses, such as wagon painting, and while they are inferior to the true mercury vermilion, from the fact that they fade on exposure, yet they are a fairly satisfactory substitute as long as they are protected by an exterior coating of varnish. Mercury vermilion is now used chiefly for red colors in oil paintings, lithography, etc.

The extraction of mercury from its ores.—Mercury is extracted by heating the ore in a retort or a furnace; the metal is expelled as a vapor, which is subsequently condensed in cooling chambers and collected.

Up to the present time mercury has been extracted from its ores solely by the dry process. Various chemical and electrolytic methods have been proposed repeatedly and numerous experiments made, but without commercial success.

Perhaps the development of electric current generated by waterpower in localities where the use of fuel is nearly or quite prohibitive will render profitable the extraction of the metal by some electrolytic process.

The principal ore of mercury, as already stated, is cinnabar, mercuric sulphide, accompanied at times with minute globules of native mercury. The metal may be extracted from the ore by a simple distillation, either in a retort or in a shaft furnace, and though mercury may be separated from cinnabar in numerous ways, only two methods are now used on a large scale. One is based on the decomposition of the ore at a high temperature by air, forming metallic mercury and sulphur dioxide gas in accordance with the reaction: $HgS+O_2=Hg+SO_2$ (360° C.). The other accomplishes the decomposition by the use of lime or iron which combines with the sulphur and sets free the mercury in accordance with the reactions: $4HgS+4CaO=4Hg+3CaS+CaSO_4$, and $HgS+Fe=FeS+Hg$, respectively. These chemical decompositions take place at temperatures above the boiling point of mercury so that the latter is expelled in gaseous form and subsequently condensed and collected in cooling chambers.

In present furnace practice the heat necessary for the decomposition of the ore, either with or without the admixture of lime or iron, is applied in two ways—first, by heating the ore charge in a tightly sealed iron retort, which produces the mercurial vapor undiluted with furnace gases; and second, by treatment in a large furnace, where the products of combustion come in direct contact with the ore and pass out of the furnace in the form of sulphur dioxide gas, nitrogen, and unused air, mixed with the expelled mercurial gases, from which the metal is obtained by condensation in the cooling chambers. Thus the essential difference between the two methods is that the vapors given off in the retort furnaces are entirely separate from the furnace gases of combustion. The retort method possesses the advantage of yielding the mercurial vapor in a concentrated and easily condensible form, which is more than offset, however, by the high cost of fuel and labor involved and the small size of a single charge. At present the use of iron retorts is restricted to exceptionally rich ores and mercurial soot and concentrates.

The furnaces now generally used in California are of the shaft type, into which the ore is fed continuously. There are two kinds of these furnaces—one called the "coarse-ore" furnace, used for treating lump ore, and the other the "tile" furnace for medium-sized and fine ores. There are many differences in the details of the construction of coarse-ore shaft furnaces, but in general they consist of a cylindrical brick shaft, into which the ore is charged at the top, while the cinders are removed at the bottom. The heat necessary for the reaction is supplied at or near the bottom of the shaft, the gases of combustion passing through the ore column, and, together with the liberated mercurial vapors, pass out from the furnace through a pipe at the top and are led to the condensing plant. The general type of tile furnace consists of a number of narrow rectangular shafts, each having a series of tiles inclined inward and downward and so placed alternately on the longer sides that the fine to medium sized ore (up to 3.5 inches in diameter) will follow a zigzag path in its descent, until it is finally discharged at the bottom through the drawing pit. The ore is gradually heated in its descent by the products of combustion from the

fuel burned in the fireplaces at or near the bottom of the furnace.

The condensing plant generally consists of a cooling device and a condensing chamber in which the liquefied mercury is deposited. The gases passing out from the furnace must necessarily be of a temperature higher than the boiling point of mercury (357.25° C.), and the mercury content of these gases by volume is often less than 1 per cent. In addition to the products of combustion of the fuel and the mercurial vapors, these furnace gases contain sulphur dioxide, which is derived from the decomposition of the ore, which when cooled yields acid liquors that attack ordinary materials of construction. In the construction of the condensing apparatus for the proper cooling and condensation of the mercury three factors must be taken into consideration: The distance the gas has to travel, the interior capacity of the chamber, and the area of the cooling surface. The details of adjusting the construction of the condenser to give the best results vary at each plant. The materials used in building the condensers should be nonabsorbent of mercurial vapor, good conductors of heat, not affected by acid vapors or liquors, and capable of being molded into the required form. No one substance answers all requirements. Iron is a good conductor of heat and may be easily shaped, but it does not resist the corrosive action of the acid vapors, and to overcome this disadvantage the iron pipes are often protected from corrosion by a coating of cement. Brick absorbs mercurial vapors, is attacked by acids, and is a bad conductor of heat. Wood will resist acid, but is a bad conductor of heat, and can not be placed near the furnace where the temperature of the gases is high. Glazed stoneware resists the action of acid and mercury, and may be made thin in order to offset its poor heat-conducting qualities. As with the variations in the selection of the materials of construction used, so is it with the general arrangement of the condensing plant.

Uses.—The most important commercial use of mercury is in the extraction of gold and silver from certain ores by the amalgamation process; the precious metals becoming alloyed with the mercury, form a heavy amalgam, which is separated by gravity from the fine sands and the "tailings" of the ore suspended in water. Owing to the avidity with which mercury combines with impurities, thereby becoming subdivided into innumerable minute globules which will not coalesce, considerable quantities of the metal are lost during the amalgamation process, by being held in suspension in the water, and washed away with the sands and the tailings.

In the chemical industries large quantities of mercury are used as electrodes in several electrolytic processes, notably in the electrolysis of brine to form sodium salts. The solution of salt having been decomposed by the electric current, the metallic sodium thereby set free at the cathode immediately combines with the mercury, from which the sodium is subsequently extracted by a treatment with water, forming sodium hydroxide (caustic soda). On account of its high specific gravity, and its freedom from attack by many gases, mercury is an invaluable material for the construction of liquid seals in gas collecting apparatus, for making thermometers and barometers, and for making electrical contacts in certain apparatus used in physical laboratories and industrial processes.

REVIEW OF THE QUICKSILVER INDUSTRY IN THE UNITED STATES DURING 1902.

The quicksilver deposits of commercial importance in California are situated in the Coast Range and are limited to an area bounded by Trinity county on the north and San Luis Obispo county on the south, both counties being included. During 1902 San Benito county contributed 7,289 flasks, valued at $306,096, the product being derived largely from the New Idria mine. Development work was carried on during the year at the Cerro Benito and the Pichaco mines. In Napa county the chief producer was the Napa Consolidated mine at Oat Hill. In the Knoxville district the Boston mine, formerly the Readington mine, under the control of the Boston Quicksilver Mining Company, and the Manhattan mine contributed to the output. The total production for Napa county during the year amounted to 7,300 flasks. Santa Clara county was next in the order of quantity produced, contributing 5,779 flasks. The chief producer in this county was the New Almaden mine, followed by the Guadalupe mine. The New Almaden mine is the oldest quicksilver mine in the United States. It was discovered and worked in 1824, when California was under Mexican rule, and was then known as the Chaboya mine. Later it was abandoned until 1845, and since 1850 it has been worked continuously. Furnaces were erected at the Santa Teresa and the Summit mines. San Luis Obispo county supplied 2,546 flasks, the chief producer being the Karl Quicksilver Mining Company. A new Scott furnace was installed and put in operation at the Oceanic mine, and development work was actively carried on at a number of smaller properties, notably the Alice, Modoc, Libertad, Madrone, Pine Mountain, and Stayton mines. Lake county furnished 3,797 flasks, obtained chiefly from the Great Western mine. The Sulphur Bank and Abbott mines, controlled by the Empire Consolidated Quicksilver Mining Company, were in litigation during the year. The Helen mine furnished a small quota, and promising development work was done at the Bullion mine, operated by the Standard Company. From Colusa county a considerable product was obtained from the Manzanite mine, Sulphur creek, where a successful process of ore concentration was operated. In Sonoma county the chief producer was the Great Eastern Quicksilver Mining Company. The total output of the county during the year was 1,519 flasks. A number of old mines were reopened in the Pine Flat district. Other producing

mines were the Cloverdale, the Great Western, and the Socrates. Development work of the Pacific Company on property adjoining that of the Crystal Company was so satisfactory as to warrant the erection of a furnace to treat the ore. A new modified Livermore furnace was completed at the Culver Bear property. In Trinity county, which contributed a small amount to the total output during the year, the Altoona Company treated ore from the surface workings and the dumps. Considerable development work was accomplished by the Boston, Integral, and several minor concerns. The balance of the total output of California was obtained in Solano county. Several new mines were added to the list of producers during 1902; those contributing an output of 100 flasks or more being the Helen mine in Lake county, and the Silver Creek mine in Santa Clara county. Other quicksilver companies reported to have started operations in 1902 were the Monterey Quicksilver Mining Company, near Idria, San Benito county; the Modoc Chief mine, near Redding, Shasta county; the Mariposa and Elizabeth mines, and the Uncle Sam and Eureka mines, near Cambria, San Luis Obispo county; and the Summit, Adobe Valley, and Orestimba properties, in Stanislaus county. A deposit of quicksilver ore of good quality was reported in Modoc county, 25 miles east of Cedarville, in the extreme northwestern part of the state—an entirely new section for the occurrence of cinnabar.

As to the future of the quicksilver mining industry of California the larger and better known mines have in a measure been worked out, and it is hardly within the range of probability that other mines equal in extent to the New Almaden or the New Idria will be discovered. Yet, on the other hand, there are many smaller mines which, by contributing from 20 to 300 flasks each per month, supply a considerable quantity of metal in the aggregate. Furthermore, the improvement in metallurgical and mining practices during recent years, which permits the profitable treatment of very lean ores, will probably maintain the quicksilver industry in an important economic position for many years to come. It is stated in general that quicksilver can be produced in California at a mining and smelting cost of $3 per ton of ore, which renders it possible to treat with profit ores containing from 0.3 to 0.6 per cent of quicksilver; in a few cases it is possible to treat even lower grade ores and yet make a profit. The general statement is made that a modern furnace, operating on average ores, produces quicksilver at a cost of $35 per flask not including interest on capital invested in the plant and property, or the cost of development work at the mine.

In Oregon the sole producer of quicksilver in recent years has been the Black Butte Quicksilver Mining Company, which opened a quicksilver mine in 1898 on a spur of the Cascade mountains at Black Butte, Lane county. A modern 40-ton shaft furnace of the inclined shelf type was installed, but after a few months it was closed for alterations, the condensation of the quicksilver being too imperfect to render the smelting profitable. Operations were resumed in 1900. In that year the above-named company acquired the Elkhead mine, in Douglas county, 5 miles from Black Butte; this mine was equipped with a 10-ton Scott furnace. Considerable development work has been reported by this concern, but the operations have not been entirely successful, as only 75 flasks of quicksilver were produced in 1901 and none in 1902. The ore of the Black Butte mine is of low grade, the average rarely exceeding one-half of 1 per cent of quicksilver.

The principal operating companies in Texas in 1902 were the Marfa and Mariposa Mining Company, with three 10-ton Scott furnaces; the Terlingua Mining Company, with one 40-ton Scott furnace; and the Colquit-Tigner Mining Company, with one 10-ton Scott furnace.

The cinnabar deposits of California Hill, Brewster county, near Terlingua post-office, 90 miles southeast of Marfa, were known to the Comanche Indians, who used them as a vermilion pigment. The knowledge of these deposits, however, was not recorded until 1894, when several Mexicans found a few pieces of cinnabar float and took them to San Carlos, on the Mexican side of the Rio Grande, whence they were sent to Chihuahua, and their mineralogical character determined. Mr. George W. Wanless, of the Rio Grande Smelting Works, and Mr. Charles Allen, of Socorro, N. Mex., under the direction of the Mexicans, found the veins and located the first mineral claims. Shortly after this Prof. William P. Blake described these deposits under the title "Cinnabar in Texas,"[1] the first important article concerning this subject on record. Considerable prospecting work was carried on in the district, but it was not until 1898 that the metal was produced in commercial quantities. In that year Lindheim & Co. made a few flasks of quicksilver in a crude furnace at Terlingua. Other concerns became interested in the development of the quicksilver deposits, and the output of the region was 270 flasks in 1899, 750 flasks in 1900, 2,932 flasks in 1901, and 5,319 flasks in 1902, thus making a total output of 9,271 flasks.

The deposits of cinnabar at Terlingua are of two classes; one occurs in hard and durable limestone and the other in soft and friable argillaceous beds. The ores are cinnabar, mercury, yellow sulphide, and terlinguaite, and contain in addition several other mercury minerals, such as calomel, eglestonite, and montroydite, which, on account of their rarity, are of scientific interest only. Cinnabar is the principal mineral and is usually mixed with clay or iron oxide. Native mercury is present in several localities in the district, occurring in the interstices of crystalline calcite, and a single cavity in the calcite veins has yielded as much as

[1] Transactions of the American Institute of Mining Engineers, Vol. XXV (1895), pages 68 to 76.

20 pounds of the native metal. The associated gangue is composed of calcite, aragonite, gypsum, and occasionally a little barite; iron oxide, pyrite, and occasionally arsenic and manganese minerals.

The methods of mining in the Terlingua district up to the present time have been extremely crude. The workings have been confined mainly to the open cuts on the surface, but a few shafts have been sunk to a depth of from eighty to ninety feet and the ore obtained by drifting along the vein. The material mined is carried to the surface in rawhide buckets on the backs of Mexican miners, who climb notched-pole ladders with great agility. The veins are generally quite narrow, often less than one foot in width. The mined ore is sorted by hand, arranged into piles according to richness, and transported to the furnace plant, where it is first crushed in a Blake crusher, operated by gas engines, which are more convenient than steam engines on account of the lack of water and fuel. The crushed ore is then conveyed to the ore bins, which are situated above the level of the furnace, and from there, as required, it is dumped into cars and charged into the furnace through hoppers.

Formerly the very rich ore was treated in a retort, a method so wasteful and entailing such costly repairs that it has been supplanted almost entirely by shaft furnaces of the continuous type similar to the Scott-Hüttner furnace used in California. The greater part of the ore is treated in a shaft furnace by air oxidation, in some cases lime being added to aid in the decomposition of the sulphide. A very small proportion, consisting of extremely rich pieces, is treated in a furnace of the retort type.

The development of the quicksilver mines in this region has been seriously hampered by the scarcity of water and the lack of fuel, mesquite wood being about the sole supply of the latter. However, coal and asphaltum have been found within a few miles of Terlingua, and there is a possibility that oil may be discovered, as the formation closely resembles that of the Corsicana oil fields.

THE QUICKSILVER INDUSTRY IN FOREIGN COUNTRIES.

In Spain, 90 per cent of the total production of quicksilver is obtained from the Almaden mines, in the province of Ciudad Real, which have been worked intermittently during the past two thousand years. The mines are owned by the Government, and the output is controlled by the Rothschilds, who have been operating the mines under a ten-year concession, which was continued in 1900. The ores are very rich, averaging about 8 per cent of metal. The furnaces are not operated during the hot season, from May to September. Mining is conducted with a view to permanency, and masonry is freely used in the various galleries and chambers of the mines. It was not until 1896 that machine drills were installed.

In Austria, the cinnabar deposits of Idria, in Krain, were first mined in 1490, and shortly afterwards were placed under Government ownership and supervision. These mines furnish by far the greater part of the total output of quicksilver in Austria, only a small quantity being supplied by the mines in Hungary. The ore of the Idria mines is separated by hand into three classes, namely, (1) a small proportion of high grade ore, containing about 8.5 per cent of mercury; (2) coarse ore, containing about thirty-five hundredths of 1 per cent of mercury; and (3) fine ore, containing sixty-five hundredths of 1 per cent of mercury. In recent years the annual average content of the concentrated ore treated in the furnaces has varied from seventy-five hundredths of 1 per cent to 1 per cent of mercury.

In Russia, the entire output of quicksilver is obtained from the mines of A. Auerbach & Co., situated near Nikitovka, on the Kursk-Kharkov Railroad, government of Ekaterinoslav, in the southern part of European Russia. In ancient times these deposits were exploited by the Greeks, but the present industry was not inaugurated until 1883. The average content of mercury in the ores extracted approximates four-tenths of 1 per cent.

In Italy, the important quicksilver producers are the Castelazara and Ripa mines in the Monte Amiata district, and the Vallalta mine in the province of Venice. The mines at Monte Amiata were originally worked by the Etruscans, and active operations are on record for the period from 1000 to 1200 A. D. The present industry began at Siele in 1846 and at Carnucchi in 1879. The ores average from three-tenths to six-tenths of 1 per cent of mercury and are treated in furnaces of modern construction. A detailed description of the furnace practice at Monte Amiata is published in The Mineral Industry, Vol. VI, pages 576 to 582.

In Mexico, the principal quicksilver producers are the Huitzuco mines, 50 miles north of Tixtla, in the state of Guerrero, and the mines at Guadalcazar. The Huitzuco deposits were first exploited in 1874 and since 1885 they have contributed annually an output of from 2,000 to 3,000 flasks of quicksilver. The ores average from six-tenths of 1 per cent to 1 per cent of mercury, and the cost of labor and fuel is so small that ores averaging as low as three-tenths of 1 per cent of the metal can be treated profitably. The methods of mining and smelting are very primitive, and the amount of metal extracted by the furnace treatment rarely exceeds one-half of the quantity present in the ore. The mines at Guadalcazar, 70 miles northeast of San Luis Potosi, have been worked by two concerns, the Compañía de Minas de Azogue de Guadalcazar and the Compañía de Nueva Potosí. The ores in this district, which contain an average of from 2 to 3.5 per cent of mercury, are smelted in a retort furnace provided with dust boxes, condensers, and a number of brick settling chambers equipped with baffle plates. The smelting process is primitive and wasteful, yet labor and fuel are so cheap

that the operations are carried on with financial profit. The old mines, worked by the Nueva Potosi Company, are reported to contain immense bodies of easily accessible cinnabar ore, carrying an average of 1 per cent of mercury. The plant of this company is equipped with two 6-ton furnaces.

In China, Australia (New South Wales), Algeria (Taghit), Brazil, Peru, and Colombia deposits of cinnabar have been reported from time to time, but in general, because of the inaccessibility of the various districts in which the deposits are located, they still await development. A small output of quicksilver was obtained early in 1902 by an English company operating the cinnabar deposits in the province of Kweichau in southwestern China.

Table 8 shows in detail the statistics of the quicksilver industry for 1902.

TABLE 8.—*Detailed summary: 1902.*

Number of mines	41
Number of operators	[1] 37
Character of ownership:	
Individual	9
Firm	7
Incorporated company	21

PLATINUM

PLATINUM.

By David T. Day, Ph. D.

Occurrence.—At the time of the Eleventh Census platinum was known to occur in the United States in the following localities: California—Butte, Del Norte, Humboldt, Mendocino, Plumas, Sierra, and Trinity counties; Idaho—Wood river country; New York—near Plattsburg; North Carolina—Burke and Rutherford counties; and Oregon—Coos, Curry, Josephine, and Lane counties. In addition to these localities in the United States, there was a platinum product greater than that from the United States which helped to supply the American market from the region of Granite creek, British Columbia, and the copper ores from the Sudbury district of Canada also brought in some platinum and palladium in the nickel-copper matte imported into the United States.

Associated with these platinum ores were occasionally found the allied metals—osmium, iridium, and palladium.

About 1898 the demand for platinum became more considerable and the search for it, and especially for the allied metal osmium, became vigorous. It resulted in much prospecting in the Eastern states, as well as in the West, and many assays of supposed platinum ores, made by Mr. A. W. Johnston,[1] showed that certain rocks in eastern Pennsylvania, eastern New York, and in many other localities contained traces of platinum.

The one event of importance in the development of the platinum industry in the United States was the discovery by Dr. L. D. Godshall, manager of the Boston and Wyoming Smelter, at Encampment,[2] that the copper ores and matte of the Rambler mine, Grand Encampment district of Wyoming, contained platinum and palladium. These observations were confirmed by Professors Wells and Penfield, of Yale University,[3] who separated sperrylite (platinum diarsenide) from this Rambler ore. Further investigations by Mr. Johnston and Professor Kemp showed that the ore of the Rambler mine contains platinum intimately mixed with all the copper ores and even the chalcopyrite, which apparently was the original copper ore in this mine, also contains platinum. This confirms an observation of the writer in 1899 to the effect that platinum occurs in the pyrite grains found in certain hydraulic mines on the Trinity river in California, notably in the mine of Mr. F. Huertevant. These observations have led the searchers for platinum to examine a great many deposits of pyrite in the United States with the hope of finding them commercially rich in platinum, however, without commercial result, so far as the writer is informed. This work is referred to, however, as indicating a direction of search for platinum which may yet prove profitable.

At the time of the Twelfth Census, therefore, the supply of platinum to the United States market, in addition to the importations from Russia and small importations from South America, consisted in the supply of platinum obtained from the localities in California and Oregon mentioned above, a small product from the Granite creek district, British Columbia, and a more considerable product obtained in refining the nickel-copper matte from the Sudbury district of Canada. The platinum deposits of Russia, which afford the principal supply of the world, have lately been described by Mr. Chester V. Purington in the Engineering and Mining Journal, Vol. LXXVII, page 720. A complete description of the occurrence of platinum in all parts of the world is given by Prof. J. F. Kemp, of Columbia College, New York, in Bulletin 193, United States Geological Survey.

The writer made an investigation in 1899 as to the proportions of platinum, osmium, and iridosmium present with gold in various parts of the West, and, supplementary to this, Dr. Waldron Shapleigh determined the proportion of osmium to platinum in many of the same samples, the results of which are given in the following statement:[4]

		Highest per cent.	Lowest per cent.
Beegum district, Shasta county, Cal.	Platinum	20.0	13.5
	Other platinum metals[1]	84.0	79.0
Hayfork district, Trinity county, Cal.	Platinum	73.0	30.0
	Other platinum metals	58.0	18.0
Trinity river district, Trinity county, Cal.	Platinum	27.0	15.0
	Other platinum metals	80.0	72.0
Crescent City, Del Norte county, Cal.	Platinum	11.0	8.0
	Other platinum metals	83.0	46.0
Port Orford, Curry county, Oreg.	Platinum	47.0	15.0
	Other platinum metals	83.0	23.0

[1] The "other platinum metals" include iridium, osmium, ruthenium, rhodium, and palladium.

Production.—From the domestic ores in the United States the product during 1902 was 94 ounces, valued at $1,814. This was obtained as a side product in placer gold mining, and as the production is entirely dependent upon the more important production of gold this great decrease in the quantity of the platinum produced, as compared with 1,408 ounces in 1901, is easily understood. In fact, the product during the last few years has varied most widely both in quantity and in the value of the product. The variation in value has been due not only to the real fluctuation and gradual increase in the price of refined platinum, but particularly to the fact that the value given has been that of the crude grains as collected and which vary widely in their contents of pure platinum. In addition to the platinum product of 1902, 20 fine ounces of iridium were obtained. In 1901 the corresponding product was 253 ounces of iridium.

The production of platinum in previous years, as collected by the United States Geological Survey, is quoted in the following table:

TABLE 1.—*Production of crude platinum in the United States, 1880 to 1900, and of refined metal from domestic ores in 1901 and 1902.*[1]

YEAR.	Quantity (ounces).	Value.	YEAR.	Quantity (ounces).	Value.
1880	100	$400	1892	80	$550
1881	100	400	1893	75	517
1882	200	600	1894	100	600
1883	200	600	1895	150	900
1884	150	450	1896	163	944
1885	250	187	1897	150	900
1886	50	100	1898	225	3,375
1887	448	1,838	1899	300	1,800
1888	500	2,000	1900	400	2,500
1889	500	2,000	1901	1,408	27,526
1890	600	2,500	1902	94	1,874
1891	100	500			

[1] The chief variations in price have been due to the quality of the crude grains. In 1901 and 1902, however, the average price for the refined metal has been given.

Of the total production of platinum in the world, about 90 per cent comes from Russia, with the remainder divided among Colombia, South America; New South Wales, Australia; the United States; and Canada. The average annual product in Russia, as is shown in the following table, was 104,023.6 ounces for the ten years 1881 to 1890, inclusive, and 183,376 ounces for the eleven years 1891 to 1901, inclusive.

TABLE 2.—*Production of platinum in Russia: 1824 to 1901.*

1901	[3] 203,283	386	.....

[1] The pood is estimated at 526.64 ounces.
[2] Taken from the Russian Journal of Financial Statistics, 1901.
[3] Taken from the Viestnik Finansov (Messenger of Finance), No. 50, 1903.

Prices.—Since the close of 1899 the price of platinum has steadily increased, reaching its maximum value in January, 1902, when the price in New York was $20 to $21 per ounce for ingot platinum. The price fell to $19.50 in February, and in June to $19, which price prevailed to the close of the year. Best hammered platinum was quoted as follows: January, 1902, 82 cents per gram; June, 76 cents; July, 74 cents; August, 73.5 cents; and December, 72.5 cents. Osmiridium is quoted at from $6 to $10 per ounce. This gradual increase in the price of platinum during the past ten years is due to the fact that there has been found no metal or alloy which will take the place of platinum, and also to the fact that there is such a limited supply and increased demand.

The price of platinum is practically determined by Johnson, Matthey & Co., of London, who are refiners of a large portion of the Russian output.

Imports.—The following table gives the imports of platinum into the United States from 1880 to 1902, as reported by the Bureau of Statistics:

TABLE 3.—*Platinum imported and entered for consumption in the United States: 1880 to 1902.*

COAL

COAL.

By Edward W. Parker.

The census of mines and quarries taken under the act providing for the Twelfth Census—the first of the twentieth century—found the United States firmly established as the principal coal producer of the world. At the taking of the Tenth and Eleventh censuses the United States was second in coal producing importance, with Great Britain first. At the Ninth Census it was exceeded in production by both Great Britain and Germany.

During the calendar year 1902, which is the period covered by the Twelfth Census of the mining industry, there were 27 states and 3 territories which contributed to the coal production of the United States. Of this number there were 5 in each of which the production amounted to less than 100,000 tons; there were 4 others in which the production was less than 1,000,000 tons; 5 states produced more than 10,000,000 tons each, and 1, Pennsylvania, produced more than 100,000,000 tons.

According to the character of the output, the coal fields of the United States conveniently fell under two great divisions, the anthracite and the bituminous. The areas from which the bulk of the anthracite is obtained are located in the eastern part of Pennsylvania, and ordinarily when reference is made to the anthracite fields of the United States those of eastern Pennsylvania are meant. There are, however, two small areas in the Rocky mountain region where true anthracite is produced in small quantities. One of these areas is in Gunnison county, Colo., the other in Santa Fe county, N. Mex. But, although the product of these two localities is true anthracite, the quantity obtained is so small that it is customary to include it with the bituminous production, and it is so included in this report.

The bituminous coal production shown here includes, in addition to the true bituminous coals, coking or non-coking, such varieties as semianthracite, semibituminous, cannel, splint, and block coals, and lignite or brown coal.

The following table is a comparative summary of the statistics of coal production as reported for the several census years from 1850 to 1902, inclusive:

Table 1.—COMPARATIVE SUMMARY: 1850 TO 1902.

	1902	1889	1880	1870	1860	1850
Number of mines	5,986	[1] 12,552	[2] 3,294	[2] 1,566	[2] 622	[2] 510
Number of operators	4,528	[3]	[3]	[3]	[3]	[3]
Salaried officials, clerks, etc.:						
Number	17,427	[4] 2,936	1,423	[5]	[5]	[5]
Salaries	$17,419,217	$2,193,870	[6]	[5]	[5]	[5]
Wage-earners:						
Average number	350,329	[4] 296,623	169,444	94,754	36,486	15,118
Wages	$220,198,401	$106,937,058	[6] $55,276,055	$44,316,491	$9,650,264	$4,069,188
Contract work	$1,650,535	$3,155,171	[3]	[3]	[3]	[3]
Miscellaneous expenses	$26,081,698	$15,421,591	[3]	[3]	[3]	[3]
Cost of supplies and materials	$37,539,702	$18,828,590	$11,589,091	$5,668,955	$2,752,972	$246,414
Product:						
Quantity, short tons	301,590,439	141,229,513	71,481,570	36,807,333	14,333,922	6,445,681
Value	$367,032,069	$160,226,328	$95,740,396	$73,524,972	$20,243,637	$7,173,750

[1] Includes 9,969 "local" mines (9,920 bituminous and 49 anthracite) for which there are no statistics for labor and expenditures; production of same, 2,889,286 short tons.
[2] Establishments.
[3] Not reported.
[4] Foremen included as wage-earners.
[5] Not reported separately.
[6] Salaries included in wages.

The following table shows the comparative statistics for the anthracite and bituminous coal industries, separately and combined, for 1889 and 1902:

TABLE 2.—COMPARATIVE SUMMARY: 1902 AND 1889.

	TOTAL.		BITUMINOUS.		ANTHRACITE.	
	1902	1889	1902	1889	1902	1889

Miscellaneous expenses	$26,081,698	$15,421,591	$16,774,459	$6,742,221	$9,307,239	$8,679,370
Cost of supplies and materials	$37,539,702	$18,828,590	$24,798,922	$7,994,210	$12,740,780	$10,834,380
Product:						
Quantity, short tons	301,590,439	141,229,513	260,216,844	95,629,026	41,373,595	45,600,487
Value	$367,032,069	$160,226,323	$290,858,483	$94,346,809	$76,173,586	$65,879,514

[1] Includes 9,969 "local" mines (9,920 bituminous and 49 anthracite) for which there are no statistics for labor and expenditures; production of same, 2,889,286 short tons.
[2] Not reported.
[3] Foremen included as wage-earners.

Two pronounced discrepancies appear in the foregoing tables. The first of these is the marked decrease in the number of mines reported for 1902, as compared with 1889. This decrease is due to the elimination, at the Twelfth Census, of a large number of small banks producing an insignificant amount of coal for purely local consumption, which were included in the previous census. At the taking of the Eleventh Census it was possible to make use of the enumerators to secure reports from these unimportant producers, but as the mining investigation at the Twelfth Census was not taken for the same year as that of population and manufactures, it was not possible to secure the services of enumerators to get the returns from these widely distributed and unimportant sources. Neither was it possible to obtain anything like complete reports by correspondence, and to have employed special agents for a complete canvass would have entailed an expense entirely out of proportion to the value of the results to be accomplished. The output from these small banks amounts to less than 1 per cent of the total, and to have made a complete canvass would have increased the cost of the investigation by probably 100 per cent. It would also have required a much longer time than could be allowed in order to complete the report within the time prescribed by law.

The second discrepancy requiring explanation is that existing between the number of wage-earners reported for 1902 and 1889. The difference is particularly noticeable in the statistics of anthracite production, where the number of wage-earners in 1902 appears to have been only 56.3 per cent of the number employed in 1889. In the bituminous mines, which increased 172.1 per cent in production, the number of wage-earners appears to have increased only 62.4 per cent. This makes it appear that in 1902 there were 861 tons of coal produced for each wage-earner employed, as compared with 476 tons in 1889. The reason for this is in part that, following the custom employed in the other reports for the Twelfth Census, the working time was assumed to have been three hundred days in the year, and the number of wage-earners had been equated in accordance with this assumption. In 1889 the average number was calculated for the actual time the mines were in operation and not for the whole year. The report of the United States Geological Survey, which has not been equated after the manner of the Twelfth Census, shows the average number of employees to have been 148,141 in the anthracite mines and 370,056 in the bituminous mines. The average time worked was one hundred and sixteen days in the anthracite mines and two hundred and thirty days in the bituminous mines. The total number of men employed, according to the report of the Survey, was 518,197, and the general average time worked was one hundred and ninety-seven days.

It is to be noted that the statistics for 1902 show a marked increase over 1889, both in the number of salaried officials and in the amount paid in salaries. This is explained by the fact that in 1889 only the salaried force employed at or in the immediate vicinity of the mines was included. On the other hand, officials and salaried employees in central offices or at a distance from the mines were included at the Twelfth Census. In 1889 the office forces at the mines numbered 2,936 persons, who were paid $2,193,870 in salaries. The salaried list at the census of 1902 included 17,427 persons who received $17,419,217. Comparable statistics for the two censuses include those for wages, for contract work, for miscellaneous expenses, and for sup-

plies and materials. In 1889 these items aggregated $144,342,410, and in 1902, $285,470,336, making an increase for the period included between those dates of $141,127,926, or 97.8 per cent. During the same period, however, there was an increase of 129.1 per cent in the value of the product and of 113.5 per cent in the tonnage, due to the unusual conditions of the market in 1902. The foregoing statistics of expense do not include expenditures connected with the marketing of the product.

The following table shows the details of the capitalization of the incorporated companies operating coal mines, anthracite and bituminous:

TABLE 3.—*Capitalization of incorporated companies: 1902.*

	Total.	Anthracite.	Bituminous.
Number of incorporated companies	1,593	76	1,517
Number reporting capitalization	1,519	69	1,450
Capital stock and bonds issued	$797,750,237	$142,032,212	$655,718,025
Capital stock:			
Total authorized—			
Number of shares	30,883,929	1,076,946	29,806,983
Par value	$653,855,920	$59,749,350	$594,106,570
Total issued—			
Number of shares	20,290,475	981,461	19,309,014
Par value	$568,906,676	$55,482,490	$513,424,186
Dividends paid	$19,296,300	$1,936,459	$17,359,841
Common—			
Authorized—			
Number of shares	29,480,914	1,065,346	28,415,568

Issued—			
Number of shares	19,011,108	973,560	18,037,548
Par value	$498,441,649	$54,692,390	$443,749,259
Dividends paid	$15,230,787	$1,933,251	$13,297,536
Preferred—			
Authorized—			
Number of shares	1,403,015	11,600	1,391,415
Par value	$76,510,207	$1,160,000	$75,350,207
Issued—			
Number of shares	1,279,367	7,901	1,271,466
Par value	$70,465,027	$790,100	$69,674,927
Dividends paid	$4,065,513	$3,208	$4,062,305
Bonds:			
Authorized—			
Number	276,036	71,879	204,157
Par value	$241,418,778	$87,925,222	$153,493,556
Issued—			
Number	259,484	70,454	189,030
Par value	$228,843,561	$86,549,722	$142,293,839
Interest paid	$9,904,973	$3,789,145	$6,115,828
Assessments levied	$4,100,380	$1,797,319	$2,303,061

The total number of shares of common and preferred stock issued by all coal mining companies was 20,290,475, having a par value of $568,906,676, on which dividends were paid to the amount of $19,296,300, or 3.39 per cent. Deducting assessments levied the net dividends paid amounted to $15,195,920, or 2.67 per cent on the capital stock issued. The total par value of the stock of the anthracite companies was $55,482,490, on which dividends amounting to $1,936,459, or 3.49 per cent, were paid. The par value of the total stock issue of the bituminous coal companies was $513,424,186, on which dividends were paid to the amount of $17,359,841, or 3.38 per cent.

Employees and wages.—The average number of wage-earners employed during each month is shown in Table 4, for the coal industry as a whole as well as for the anthracite and bituminous mines separately.

TABLE 4.—*Average number of wage-earners employed during each month: 1902.*

	Total.	Anthracite.	Bituminous.
Total average number	350,329	69,691	280,638
Men 16 years and over:			
January	394,841	110,018	284,823

November	13,631	7,804	5,827
December	14,065	8,209	5,856

The effect of the anthracite coal strike on the employment of labor in that industry is clearly shown in the above table.

For more than five months, or from May 12 to October 25, mining operations were almost entirely suspended in the anthracite region, the idleness being due to a strike among the mine workers. On account of the practically complete cutting off of the supply of anthracite, there existed, during the latter half of the year, a scarcity of fuel which amounted in many parts of the Eastern states to an actual famine. The strike was finally settled by the friendly and personal intervention of the President of the United States, who with the consent of the operators and the leaders of the striking miners appointed a commission "to inquire into, consider, and pass upon the questions in connection with the strike in the anthracite region, and the causes from which the controversy arose." Operations were resumed immediately upon the appointment of the commission, but owing to the necessity for repairs and for pumping water from many of the mines, occasioned by the long period of idleness, it was several weeks before normal conditions were restored.[1]

The average number of all wage-earners employed during July, 6,493—which was the minimum—closely

[1]This matter is thus briefly referred to here, partly because of its historic interest, but chiefly because the conditions are reflected in the statistics presented in this report and require some explanation. The report of the commission has been published and can be had upon application to the United States Commissioner of Labor. It contains some interesting statistical tables on the subject of wages paid to the different classes of labor, on the cost of living in the anthracite region, and other details which will be found useful to anyone interested in the study of the anthracite industry.

approximates the average number of engineers, firemen, and other mechanics for the year, which was 6,513. The bituminous industry also shows that the minimum number was employed in July; the range, however, was not great, the minimum being less than 9 per cent below the average for the year.

Of all employees engaged in the coal industry, 19.9 per cent were employed in anthracite mines, and 80.1 per cent in bituminous mines, while employees in the anthracite industry received only 17.5 per cent of the total amount paid in salaries and wages, leaving 82.5 per cent for those engaged in the bituminous industry.

The percentages of wage-earners employed above and below ground and the percentages for the several classes of wage-earners in the two branches of the coal industry are shown in the following statement:

Percentages of wage-earners above and below ground and by occupations: 1902.

	Anthracite.	Bituminous.
Wage-earners	100.0	100.0
Above ground	40.1	12.9
Below ground	59.9	87.1
Above ground	100.0	100.0
Engineers, firemen, and other mechanics	23.3	37.5
Boys under 16 years	13.7	2.3
All other wage-earners	63.0	60.2
Below ground	100.0	100.0
Miners	42.6	77.5
Miners' helpers	16.6	1.5
Boys under 16 years	1.8	1.9
All other wage-earners	39.0	19.1

Production.—During the calendar year 1902 the coal production of the United States amounted to 301,590,439 short tons, valued at the mines at $367,032,069. Of this total, 41,373,595 tons, valued at $76,173,586, were Pennsylvania anthracite, and 260,216,844 tons, valued at $290,858,483, were bituminous and lignite coal. Compared with the output reported at the Eleventh Census, the total production of coal in the United States in 1902 showed an increase of 160,360,926 short tons, or 113.5 per cent. This increase was all in the production of bituminous coal and lignite, for, on account of labor troubles in the anthracite fields of Pennsylvania, the output of anthracite in 1902 was restricted to about two-thirds of the normal production, and was less than that of 1889 by 4,226,892 short tons, or 9.3 per cent.

The production of bituminous coal in 1902 was abnormally stimulated by the scarcity of anthracite. Owing to the continuous activity and expansion in nearly all lines of manufactures, an increased production of bituminous coal would naturally have resulted, but would probably not have reached the amount it did had it not been for the fuel famine, especially in the Eastern states. On the other hand, conditions would have been greatly improved and the production and supply of bituminous coal would have been considerably increased had the transportation companies been able to meet the demands put upon them. The productive capacity of the bituminous mines could easily have supplied all the fuel needed had it been possible to get the product promptly to the consumer.

The production of bituminous coal in 1902 amounted to 260,216,844 short tons, valued at the mines at $290,858,483. As compared with 1889, when the production was 95,629,026 short tons, valued at $94,346,809, these figures show an increase of 164,587,818 short tons, or 172.1 per cent in amount, and of $196,511,674, or 208.3 per cent in value. The relatively higher value of the product in 1902 was due partly to the improved industrial conditions in that year, and partly to the increase in prices naturally resulting from the curtailment in anthracite production. The average price per short ton for bituminous coal in 1902 was $1.12, as compared with 99 cents in 1889.

The following table is a summary of production of anthracite and bituminous coal as reported at the last six censuses:

TABLE 5.—PRODUCTION OF ANTHRACITE AND BITUMINOUS COAL: 1850 TO 1902.

[Short tons.]

	1902	1889	1880	1870	1860	1850
Total	301,590,439	141,229,513	71,481,570	36,807,333	14,333,922	6,445,681
Anthracite	[1] 41,467,532	[2] 45,600,487	28,649,812	17,543,988	8,115,842	4,138,164
Per cent of total	13.7	32.3	40.1	47.7	56.6	64.2
Bituminous	260,122,907	95,629,026	42,831,758	19,263,345	6,218,080	2,307,517
Per cent of total	86.3	67.7	59.9	52.3	43.4	35.8

[1] Includes 93,937 tons of anthracite produced in Colorado and New Mexico.
[2] Includes 53,517 tons of anthracite produced in Colorado and New Mexico, and 2,000 tons of graphitic coal produced in Rhode Island.

It will be observed in the foregoing table that in 1850 the anthracite product of Pennsylvania was nearly two-thirds of the coal production of the country, and that in 1870 the production of coal in the United States was nearly equally divided between the anthracite product of Pennsylvania and the output of bituminous mines; whereas in 1902 the production of bituminous coal was 6½ times that of anthracite. Had it not been for the strike, however, the production of the anthracite fields in 1902 would probably have reached a total of about 65,000,000 tons, indicating that under normal conditions the output of bituminous coal in 1902 would have been about four times that of anthracite.

One of the interesting features connected with the coal mining industry during the last quarter of a century has been the gradual elimination of anthracite as a factor in manufacturing. Bituminous coal has largely supplanted anthracite for manufacturing purposes, even

in the Eastern states, while the latter has become more and more restricted to household consumption. For this reason the normal increase in the production of anthracite coal has been about in proportion to the increase in population, whereas the increase in bituminous production has rapidly outstripped the increase in population, as it has the increase in production of anthracite coal.

The development of the coal resources of the United States has been coincident with the rapid advancement of this country in the last few years to the front rank among the industrial nations of the world. Indeed, the country's progress has been due largely to the abundance and cheapness of its mineral fuels, chief among which is coal. Most of this development has taken place during the last two decades and has far exceeded the growth in population, indicating a rapid change from an agricultural to a manufacturing nation. A comparison of the growth in population with the increase in production presents some interesting facts in support of this statement. The Ninth Census was the first which took separate cognizance of the mining industry, but the United States Geological Survey has compiled from such records as are available an approximate statement of the annual coal production of the United States from the year when the first anthracite coal was mined in Pennsylvania (1814) to the close of 1902.

Diagram I illustrates the growth of the coal production of the country from 1830 to 1902, both in production per capita and in comparison with the increase in population.

The following table gives the population and coal production, respectively, from 1830 to 1902, with the per cent of increase during each intervening period and the average amount of coal product per unit of population. The statistics, except those for 1890 and 1902, are taken from the reports of the United States Geological Survey.

TABLE 6.—*Population and coal production: 1830 to 1902.*

CENSUS OF—	Population.	Per cent of increase.	Coal production (short tons).	Per cent of increase.	Tons of coal per unit of population.
1830	12,866,020	.....	318,072	.....	0.025
1840	17,069,453	32.7	1,785,574	461.4	0.105
1850	23,191,876	35.9	6,445,681	261.0	0.278
1860	31,443,321	35.6	16,169,736	150.9	0.514
1870	38,558,371	22.6	36,806,560	127.6	0.955
1880	50,189,209	30.1	76,157,944	106.9	1.518
1890	63,069,756	24.9	[1]141,229,613	85.4	2.255
1900	76,303,387	21.8	269,684,027	91.0	3.534
1902	[2]78,576,436	3.0	301,590,439	11.8	3.838

[1] For calendar year 1889.
[2] Estimates of population, United States Census, Bulletin No. 7, 1904.

At the taking of the census of 1820 the production of coal in this country was less than 500 tons, all of which was Pennsylvania anthracite. The population of the United States in that year was 9,638,453. In 1830, when the population had grown to 12,866,020, the production of coal amounted to 318,072 short tons. At the end of the next decade the population of the United States was 17,069,453, and the coal output was 1,785,574 short tons. The production per capita in that year (1840) was 0.105 ton. This was the first census year in which the coal production amounted to as much as 0.1 ton for each person. In 1850, when the inhabitants numbered 23,191,876, the output of coal mines amounted to only 6,445,681 short tons, or 0.28 ton for each person. The census of 1860 gave a population of 31,443,321, and the coal production was 16,169,736 short tons, or 0.51 ton per capita. When the Ninth Census was taken the coal production was still less than 1 ton for each inhabitant, the population being 38,558,371, and the coal production amounting to 36,806,560, or 0.96 ton per capita.

In 1880, when the population had increased to 50,189,209, the production of coal had grown to 76,157,944 short tons, or 1.52 tons per capita. The mining census for the calendar year 1889 showed a coal production of 141,229,613 short tons and the population census for the fiscal year ending June 30, 1890, showed a total of 63,069,756 persons, the per capita production of coal being 2.26 tons. The Twelfth Census reported a population of 76,303,387, the United States Geological Survey reporting for that year a coal production of 269,684,027 short tons, or 3.53 tons for each inhabitant. If the population for 1902 be estimated at 78,576,436, the per capita coal production is shown to have been 3.84 tons for that year.

It must be remembered that within the last thirty years, during which the coal production has so markedly outstripped the growth in population, petroleum and natural gas have been produced in enormous quantities and to the value of many millions of dollars annually. The increased output of these fuels, however, has been partly offset by a decrease in the amount of wood used for fuel, but while it is known that such a decrease has taken place, there are no statistics by which comparisons can be made.

The following comparative statement shows the average production per mine and per employee from the statistics given in Table 1:

Average production per mine and per employee for each census year: 1850 to 1902.

	1902	1889	1880	1870	1860	1850
Average product:						
Per mine, tons	50,383	[1]53,578	21,701	20,986	23,045	12,539
Per employee, tons	565	476	422	347	393	426

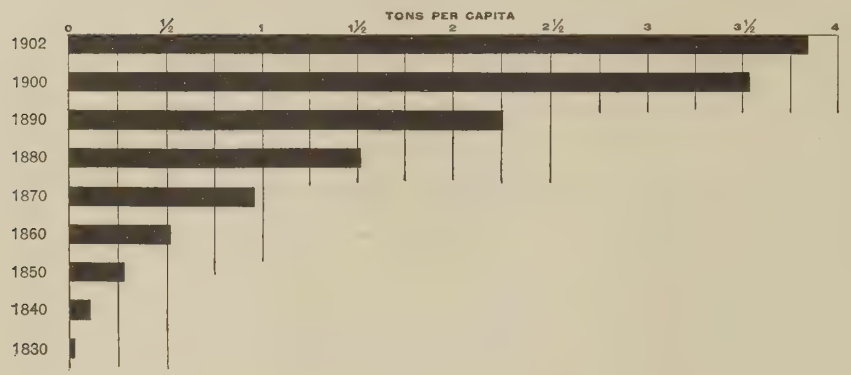
[1] Exclusive of local mines.

In all the later decades there was a steady increase in the output per employee.

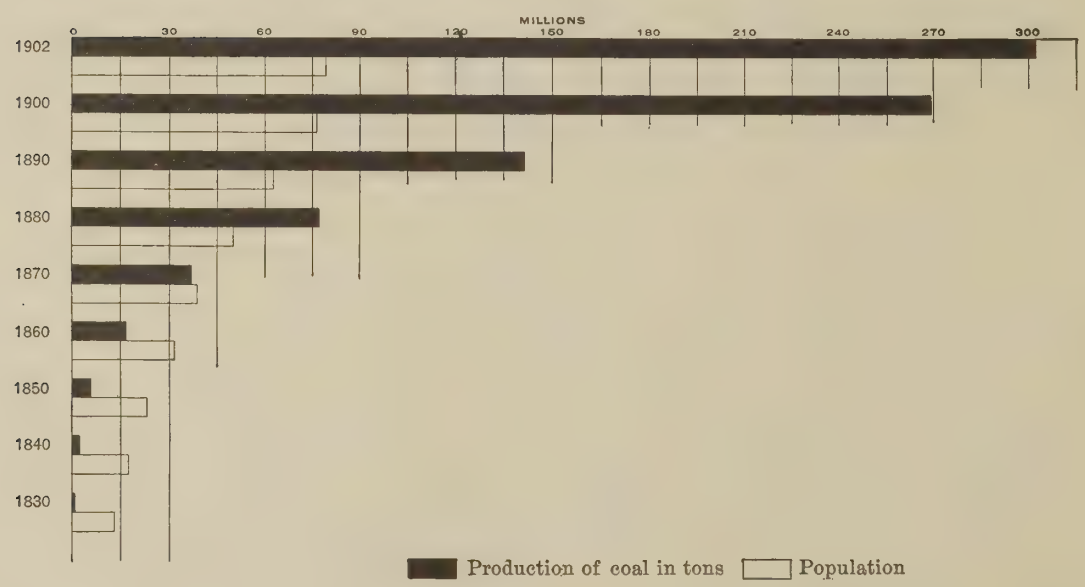
Annual statistics compiled by the United States Geological Survey show that the United States has exceeded Germany's production in every year since and including 1871, with the exception of the two years 1875 and 1876, and since and including 1899 has outranked

DIAGRAM I.—(*a*) PRODUCTION OF COAL PER CAPITA; (*b*) COMPARISON OF POPULATION WITH PRODUCTION: 1830 TO 1902.

(*a*) Production of coal per capita: 1830 to 1902.



(*b*) Comparison of population with production of coal: 1830 to 1902.



Great Britain. In 1901 and 1902 the United States exceeded in coal production the combined output of Great Britain and all its colonies and dependencies.

The following table shows the production of coal in the United States, Great Britain, Germany, and the other countries of the world in each census year from 1870 to 1902, and the same is shown graphically by Diagram II. The imports and exports of coal for the United States and the domestic production and consumption are also indicated by Diagram II.

TABLE 7.—WORLD'S PRODUCTION OF COAL, BY COUNTRIES, WITH PER CENT EACH IS OF TOTAL, AND PER CENT OF INCREASE: 1870 TO 1902.

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

[Short tons.]

COUNTRY.	1902	1889	1880	1870	INCREASE, 1870 TO 1902	
					Quantity.	Per cent.
All countries	884,803,434	531,797,039	369,413,780	238,621,068	646,182,366	270.8

Great Britain	254,346,447	198,146,731	164,605,738	123,682,935	130,663,512	105.6
Per cent of total	28.8	37.2	44.6	51.8	20.2	.....
Germany	165,826,496	93,640,500	65,177,634	37,488,312	128,338,184	342.3
Per cent of total	18.7	17.6	17.6	15.7	19.9	.....
All other countries[1]	163,040,052	98,780,195	63,472,464	40,643,261	122,396,791	301.1
Per cent of total	18.4	18.6	17.2	17.1	18.9	.....

[1] Includes Austria-Hungary (1901), 45,417,959; France, 33,286,146; Belgium (1901), 24,485,842; Russia (1901), 17,934,201; India, 8,326,049; Japan (1900), 8,187,262; Canada, 7,639,225; New South Wales, 6,655,052; Spain (1901), 3,027,992; New Zealand (1901), 1,374,955; Mexico, 782,251; South African Republic (1901), 752,116; Natal, 663,960; Queensland (1901), 604,209; Italy (1901), 469,154; Holland (1900), 352,888; Sweden, 335,907; Victoria (1901), 234,448; Cape Colony (1900), 222,265; Tasmania (1900), 48,171; China, Turkey, Servia, Portugal, United States of Colombia, Chile, Borneo and Labuan, Peru, Greece, etc., 2,240,000.

This table shows that while in a period of approximately thirty years the coal production of Great Britain had only a little more than doubled, that of the United States in 1902 was more than eight times what it was in 1870. It also shows that Germany and all other countries combined have only approximately quadrupled their production of coal in the same period.

ANTHRACITE.

The anthracite coal product herein reported is confined to the state of Pennsylvania, the small output of Colorado and New Mexico being included in the statistics for bituminous coal. The following table is a summary of the statistics for anthracite production in Pennsylvania, by counties, during 1902:

TABLE 8.—SUMMARY, PENNSYLVANIA ANTHRACITE, BY COUNTIES: 1902.

	Total.	Carbon.	Columbia.	Lackawanna.	Luzerne.	Northumberland.	Schuylkill.	Other counties.[1]

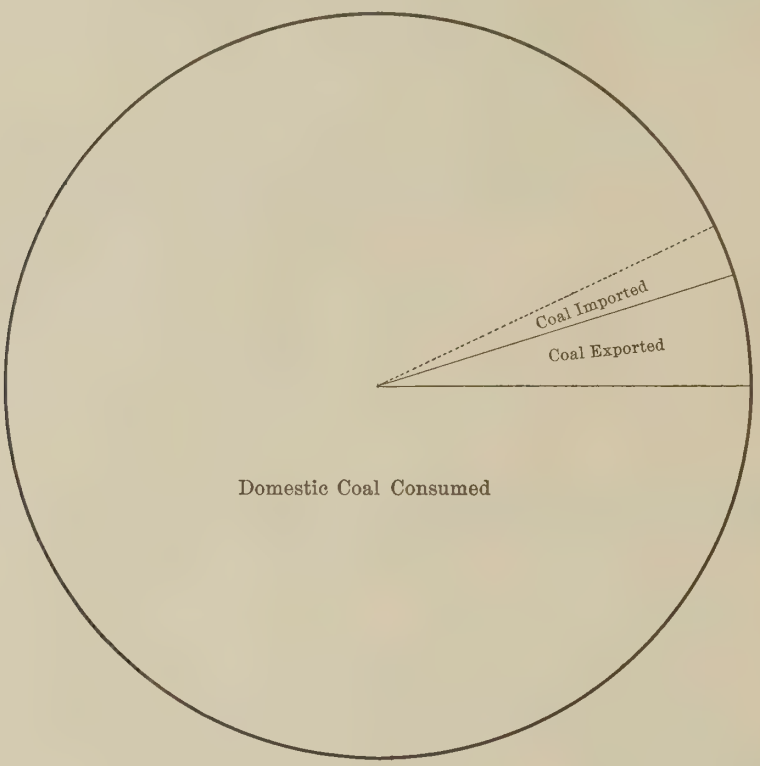
[1] Includes operators distributed as follows: Dauphin county, 2; Sullivan county, 2; Susquehanna county, 1 (2 mines).

There were 2 anthracite coal mines in Pennsylvania in the development stage for which no production was reported. One was in Luzerne county and the other in Schuylkill. These were operated by 2 of the active companies and the statistics therefor are included in the statistics for the developing bituminous coal mines of the state. There were 17 idle mines proper, distributed, by counties, as follows: Lackawanna, 1; Luzerne, 4; Northumberland, 4; and Schuylkill, 8.

Employees and wages.—In Table 9 the distribution of wage-earners according to daily rates is shown by occupations.

DIAGRAM II.—(*a*) DOMESTIC PRODUCTION AND CONSUMPTION OF COAL, 1902; (*b*) COAL PRODUCTION OF THE WORLD: 1902, 1890, 1880, AND 1870.

(*a*) Domestic production and consumption of coal: 1902.



(*b*) Coal production of the world: 1902, 1890, 1880, and 1870.

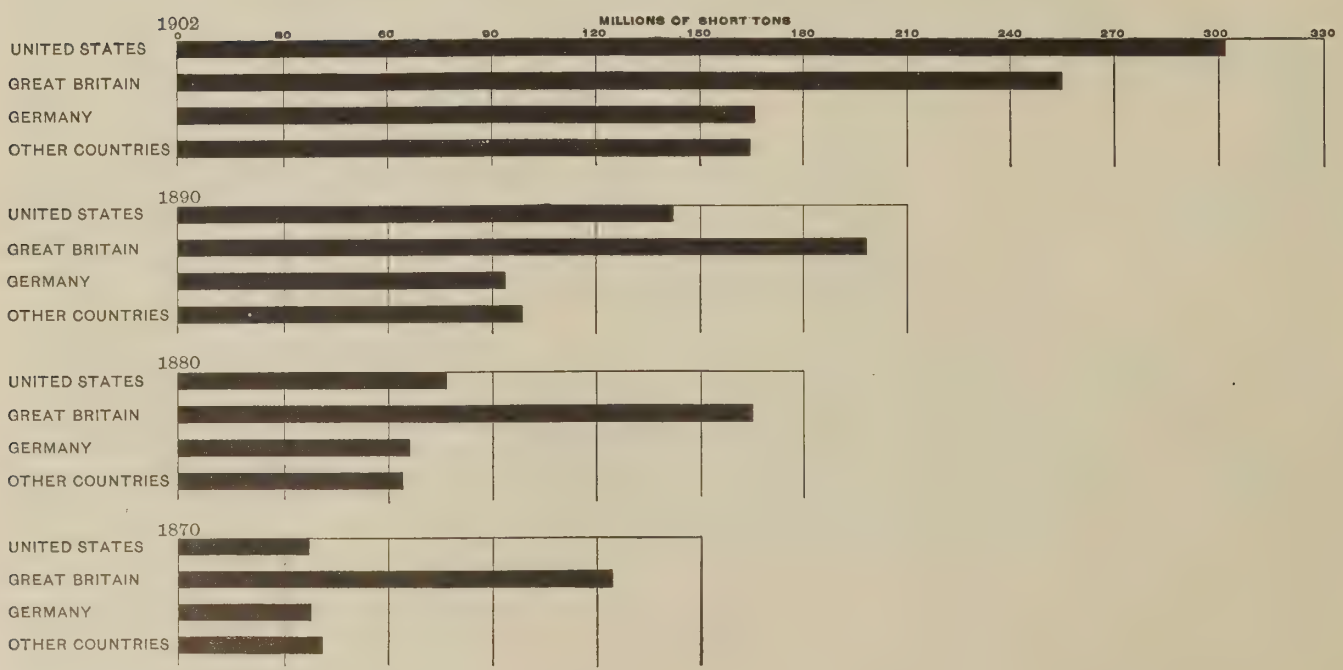


TABLE 9.—COAL, ANTHRACITE—WAGE-EARNERS AT SPECIFIED DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

[Each cumulative percentage shows the proportion of total number of persons in the given class receiving a wage as great as, or greater than, the lowest wage of the given wage group.]

[1] Less than one-tenth of 1 per cent.

As shown by the above table, the great majority of the wage-earners received from $0.50 to $2.74 per day, 62,111, or 89.1 per cent of all wage-earners having been reported at rates between those limits. But two factors somewhat peculiar to the coal industry make such generalization misleading: (1) The large number of boys employed lessens the average wage as a whole; (2) the bulk of the mining is done on a tonnage or yardage basis, the equivalent daily rate of pay for the periods reported being calculated from the amount paid and the number of miners so employed.

There were 17,767 miners reported, 25.5 per cent of all wage-earners in the industry, and there were 6,921 miners' helpers. Of the miners 15,285, or 86 per cent, were paid from $1.75 to $3.74 per day, the largest number embraced within a single rate group 3,776, or 21.3 per cent of all miners, receiving from $2.25 to $2.49 per day. There were 1,185, or 6.7 per cent, who received pay at the rate of $3.75 or more per day. A larger number of miners' helpers were included in the rate group of $1.75 to $1.99 per day than in any other group, and 91.9 per cent of the miners' helpers, or 6,361 men, were paid from $1.25 to $2.49 per day. The range of wages for 1,853 engineers, 89.8 per cent of all reported, was from $1.50 to $2.74, and of the 1,836 firemen, 1,778, or 96.8 per cent, received between $1.25 and $2.24. Of 2,613 machinists, blacksmiths, and other mechanics, 2,451, or 93.8 per cent, were paid between $1.50 and $2.74. The largest number of timbermen and track layers in one rate group, 624, or 31.6 per cent of all in this class, was paid from $1.75 to $1.99 per day, and 1,833, or 92.7 per cent, were reported at rates between $1.50 and $2.49 per day. The 4,564 boys under 16 years of age, comprised 6.5 per cent of all wage-earners. Of this number 2,006, or 44 per cent, received from $0.50 to $0.74 per day, and 4,467, or 97.9 per cent of the total number, were reported at rates between $0.50 and $1.24 per day. The group of

"all other wage-earners" comprised 45.8 per cent of the total number of wage-earners reported. Their wages ranged from less than $0.50 per day to $3.49 per day, but 83.1 per cent received from $1 to $1.99, while only 9.5 per cent received $2 per day or over and but 7.4 per cent less than $1 per day.

The following table shows the distribution of wage-earners according to daily rates of pay, by counties:

TABLE 10.—COAL, ANTHRACITE—WAGE-EARNERS AT SPECIFIED DAILY RATES OF PAY, BY COUNTIES: 1902.

[Each cumulative percentage shows the proportion of total number of persons receiving a wage as great as, or greater than, the lowest wage of the given wage group.]

[1] Includes Columbia, Dauphin, Sullivan, and Susquehanna.

[2] Less than one-tenth of 1 per cent.

In the above table the statistics are separately reported for the counties of Carbon, Lackawanna, Luzerne, Northumberland, and Schuylkill. The amount paid for contract mining, which is included in wages paid, and the average number of employees doing such work, who are included in wage-earners, are shown in the following statement:

Coal, anthracite contract mining, by counties: 1902.

	Total.	Carbon.	Lackawanna.	Luzerne.	Northumberland.	Schuylkill.	All other counties.
Amount paid	$16,572,582	$358,013	$4,756,929	$6,171,054	$1,526,805	$3,113,770	$646,011
Average number of employees	22,629	547	5,576	8,306	2,372	4,879	949

Of the total amount paid as wages to miners and miners' helpers, 92 per cent was on account of contract mining, hence the difficulty as before noted of deducing daily rates for the miners. In Carbon county the amount paid for contract mining constituted 99 per cent of wage payments to miners and miners' helpers; in Lackawanna county it constituted 96.1 per cent; in Luzerne county, 93.2 per cent; in Northumberland county, 91.6 per cent; and in Schuylkill county, 89.3 per cent.

Contract work.—Contract work does not include contract mining by the ton or otherwise, but only work done by contract in the way of tunneling, shaft sinking, etc. For this kind of work the sum of $406,421 was expended and 1,731 men were employed.

Supplies, materials, and miscellaneous expenses.—The cost of supplies and materials reported as $12,740,780, is the largest item of expense other than wages and salaries. Of the $9,307,239 expended for miscellaneous expenses, $4,359,051 was paid for royalties and rent of mines and mining plant, and $4,948,188 was for rent of offices, taxes, and other sundries.

Mechanical power.—A total of 434,220 horsepower was reported as owned by the anthracite coal operators, of which 415,827 horsepower, or 95.8 per cent, was furnished by 4,629 steam engines, 185 horsepower by 6 gas or gasoline engines, and 18,208 horsepower by 234 primary motors of other kinds. In addition electric motors to the number of 78, aggregating 5,755 horsepower, were reported as owned by the operators.

Production.—The production of anthracite in Pennsylvania during 1902 amounted to 36,940,710 long tons, which was less than that of 1889 by 3,724,442 long tons. This decrease was due solely to the strike in the anthracite region. The normal production of the region, according to the statistics compiled by the United States Geological Survey, is between 50,000,000 and 55,000,000 long tons per year. The suspension of work for more than five months cut down the production to about 60 per cent of the normal output. It must not

be considered, therefore, that the statistics of anthracite production presented here represent the normal condition of the industry.

The total production from the time coal was first mined in Pennsylvania in 1814 to the close of 1902 is estimated at a little over 1,500,000,000 short tons, or an average of nearly 18,000,000 tons a year. During the ten years from 1893 to 1902, inclusive, the average annual production has amounted to a little over 55,000,000 short tons.[1]

The anthracite areas of Pennsylvania are included in the 9 counties of Susquehanna, Lackawanna, Luzerne, Carbon, Schuylkill, Columbia, Northumberland, Dauphin, and Sullivan. The total area of the anthracite fields of Pennsylvania is about 484 square miles.

The following statement shows the percentage of production for each county:

Percentage of anthracite production.

COUNTY.	Per cent.
Total	100.0
Luzerne	34.8
Lackawanna	29.2
Schuylkill	20.8
Northumberland	7.8
Carbon	2.7
Columbia	1.8
Susquehanna	1.1
Dauphin	1.0
Sullivan	0.8

The distribution of the product for consumption, for each county, during 1902, is shown in the following table:

TABLE 11.—*Anthracite production and distribution for consumption, by counties: 1902.*

[Long tons.]

COUNTY.	Total quantity.	Shipments.	Local trade.	Used at mines.
Total	36,940,710	31,486,120	995,655	4,458,935
Luzerne	12,852,826	11,040,374	377,379	1,435,073
Lackawanna	10,779,268	9,659,014	269,678	850,576
Schuylkill	7,704,202	6,240,258	193,278	1,270,666
Northumberland	2,878,615	2,308,253	92,719	477,643
Carbon	986,201	796,791	24,621	164,789
Columbia	670,115	588,058	11,323	70,734
Susquehanna	404,248	373,451	9,792	21,005
Dauphin	369,235	194,691	13,883	160,661
Sullivan	296,000	285,230	2,982	7,788

The shipments constitute 85.2 per cent of the total production, 2.7 per cent being sold in local trade, and 12.1 per cent consumed at the mines.

The classification of the Sullivan county product as anthracite has given rise to some contention. This coal lies in an isolated district known as the Bernice basin, in the northeastern part of Sullivan county and extending into the southeastern part of Wyoming county. Its physical characteristics are more like semi-anthracite than true anthracite, but on account of its high percentage of fixed carbon and low percentage of moisture it is classed as an anthracite by the Second Pennsylvania Geological Survey, and it is so considered in this report.

In a general way the anthracite coal field may be said to be bounded on the north by the north branch of the Susquehanna river, on the east by the Delaware and Lehigh rivers, and on the west by the Susquehanna river. These rivers, together with the Schuylkill, form the drainage outlets for the region. The entire anthracite region embraces a territory of about 3,300 square miles, but less than one-sixth of this total area, or about 484 square miles, is underlaid by workable deposits of coal. The productive portion is not in a continuous area, but consists of a number of detached valleys or basins, the general trend of which is about 60° N. to 70° E. They are arranged en échelon, from NE. to SW., for a distance of 120 miles. The greatest width is 30 miles, from Mauch Chunk to Shickshinny, or 50 miles if the Bernice basin in Sullivan county be considered as a portion of the anthracite field proper.

The anthracite coal fields, exclusive of the Bernice basin, are divided into 3 general trade regions, known as the Wyoming, Lehigh, and Schuylkill. Geographically these regions are subdivided into 4 well-defined fields or basins, known as the Northern, Eastern Middle, Southern, and Western Middle. These fields or basins are again subdivided, for convenience of identification, into districts as follows:

Anthracite coal fields, by field, local district, and trade region.

COAL FIELD OR BASIN.	Local district.	Trade region.
Northern	Carbondale	Wyoming.
	Scranton	
	Pittston	
	Wilkesbarre	
	Plymouth	
	Kingston	
Eastern Middle	Green Mountain	Lehigh.
	Black Creek	
	Hazelton	
	Beaver Meadow	
Southern	Panther Creek	Schuylkill.
	East Schuylkill	
	West Schuylkill	
	Lorberry	
	Lykens Valley	
Western Middle	East Mahanoy	
	West Mahanoy	
	Shamokin	

Of the 4 geographic divisions named above, the Southern is the largest, containing 181 square miles. The Northern is the next in size, containing 176 square miles. The Western Middle, the third in size, contains 94 square miles, and the Eastern Middle, the smallest of the divisions, contains 33 square miles.

The Northern basin.—The Northern basin extends from Forest City, on the northeast, to Shickshinny, on the southwest, a distance of 55 miles, and is drained by the valleys of the Lackawanna and the Susquehanna rivers. Its maximum width is about 6 miles. This basin, which is also known as the Wyoming Trade region, was the

[1] In previous years some coal which was classed as anthracite was mined in the eastern part of Rhode Island, and in Bristol and Plymouth counties in Massachusetts. This product is, however, in reality of a graphitic quality and not anthracite. It is not now mined for fuel purposes, and the production is included with that of graphite.

last of the anthracite basins to be developed. Mining was first begun here in 1829, the shipments in that year amounting to 7,000 long tons, or 6.25 per cent of the total anthracite shipments from the region. This region gradually developed in importance until it is now the most productive portion of the anthracite coal fields. Since 1883 more than 50 per cent of the shipments have been from the Northern basin, or Wyoming region, as it is differently called. In 1902 this region contributed 61.73 per cent of the entire shipments of anthracite. From 1829 to the close of 1902 this basin or region shipped 626,798,256 long tons of 2,240 pounds, or 49.87 per cent of the entire shipments from the anthracite coal fields of Pennsylvania.

The Eastern Middle field.—This is the smallest of the 4 main geographical divisions and lies about 15 miles south of the western end of the Northern basin, from which it is separated by a mountain range and a valley. Its greatest length is about twenty-six miles and its greatest width about ten miles, the total coal area containing about thirty-three miles.

The Eastern Middle basin forms what is known as the Lehigh Trade region, and enjoys the distinction of having the earliest recorded anthracite shipments. In 1820, 365 long tons of coal were shipped from the Lehigh region, and in the eighty-three years from 1820 to 1902, inclusive, it has shipped a total of 212,039,554 long tons, or 16.87 per cent of the total anthracite shipments.

The Southern basin.—This is the largest of the anthracite coal fields, and contains about one hundred and eighty-one square miles. It extends from Mauch Chunk, on the Lehigh river, on the northeast, to Dauphin on the Susquehanna river, on the southwest. Its greatest width, at Pottsville, is eight miles, from which it gradually tapers toward the northeast and the southwest, and in the latter direction divides into 2 long narrow basins.

The Western Middle basin.—The Western Middle basin lies southwest of and adjoins the Eastern Middle. It is north of and approximately parallel with the Southern basin, to which it is contiguous for a short distance. This basin is 36 miles long, from 4 to 5 miles wide, and contains 94 square miles underlain by coal. In this basin there are 2 distinct sub-basins or divisions, known as the Mahanoy and the Shamokin, which are about equal in size, depth, and importance.

The Southern and the Western Middle basins together form what is known as the Schuylkill Trade region. The first shipments from this region, as far as known, were made in 1822, two years after the first coal was shipped from the Lehigh region. At the close of 1902 there had been shipped from the Schuylkill region 417,944,349 long tons, or 33.26 per cent of the entire anthracite shipments.

The following table shows the shipments of anthracite from the 3 trade regions for each year from the beginning of the industry, in 1820, to the close of 1902. These statistics are from the records maintained by the Bureau of Anthracite Coal Statistics. The figures do not include shipments from the Bernice basin, in Sullivan county, nor any coal sold to local trade or consumed at the collieries.

TABLE 12.—*Annual shipments from the Schuylkill, Lehigh, and Wyoming regions: 1820 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

[1] Includes Loyalsock field.

BITUMINOUS.

In 1902 the total output of the varieties of bituminous coal included in this report amounted to 260,216,844 short tons, valued at $290,858,483, as compared with 95,629,026 short tons, valued at $94,346,809, in 1889, and 42,840,751 short tons, valued at $53,466,958, in 1880.

Though the small mines numbered 826, they furnished but 196,488 tons of coal, or 0.075 per cent of the total bituminous output. They averaged 238 tons per mine, as compared with 53,879 tons, the average production of commercial mines.

A summary of the bituminous coal statistics for both commercial and small mines is presented in Table 13.

TABLE 13.—*Summary, coal, bituminous: 1902.*

	Total.	Commercial mines.	Small mines.
Number of mines	5,652	4,826	826
Number of operators	4,409	3,584	825
Salaried officials, clerks, etc.:			
Number	14,413	14,413	.....
Salaries	$14,511,924	$14,511,924	.....
Wage-earners:			
Average number	280,638	280,205	433
Wages	$181,482,288	$181,347,208	$135,080
Contract work	$1,244,114	$1,242,239	$1,875
Miscellaneous expenses	$16,774,459	$16,770,185	$4,274
Cost of supplies and materials	$24,798,922	$24,780,695	$18,227
Product:			
Quantity, short tons	260,216,844	260,020,356	196,488
Value	$290,858,483	$290,584,483	$274,000

Capital stock of incorporated companies.—The following table shows the details of capitalization of the incorporated companies operating bituminous coal mines for the United States, by states and territories:

TABLE 14.—COAL, BITUMINOUS—CAPITALIZATION OF INCORPORATED COMPANIES: 1902.

[1] Includes incorporated companies distributed as follows: Alaska, 1; North Carolina, 1.

According to this table the total number of shares, common and preferred, issued and outstanding, by incorporated bituminous coal mining companies operating in 1902, and reporting capitalization, was 19,309,014, having a par value of $513,424,186, on which dividends were paid to the amount of $17,359,841, or 3.38 per cent on the par value of the stock issued. Deducting assessments levied, $2,303,061, the net dividends paid amounted to $15,056,780, or 2.93 per cent on the capital stock.

There were 1,517 incorporated companies engaged in this branch of the coal industry, and of these 67 did not report capitalization. These nonreporting incorporated companies were distributed among 16 of the bituminous coal states, as follows: Ohio, 13; Pennsylvania, 11; West Virginia, 10; Illinois, 7; Kentucky, 5; Alabama, Colorado, and Kansas, each 3; Indiana, Michigan, Texas, and Wyoming, each 2; and Iowa, New Mexico, North Dakota, and Washington, 1 each. No dividends were reported as paid by the companies operating in Alaska, Missouri, North Carolina, North Dakota, and Oregon. The interest paid on bonds was $6,115,828, and the sum of $2,303,061 was paid in as assessments on capital stock.

Employees and wages.—The expenditures reported for salaries were $14,511,924, and for wages, $181,482,288.

In the following table is shown the distribution of the wage-earners according to their occupation and daily rates of pay:

TABLE 15.—COAL, BITUMINOUS—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

[Each cumulative percentage shows the proportion of total number of persons in the given class receiving a wage as great as, or greater than, the lowest wage of the given wage group.]

[1] Less than one-tenth of 1 per cent.

This table shows that the majority of adult wage-earners received wages between $1.75 and $2.74. Including all occupations, the largest number embraced in a single rate group was reported as receiving from $2 to $2.24 per day, 25.3 per cent falling in that group. From this rate the numbers decreased regularly as the rates of pay decreased below $2 or increased above $2.24. In the class of engineers 70.4 per cent were employed at daily rates ranging from $2 to $2.74, and in the class of firemen 73.5 per cent at rates ranging from $1.50 to $2.24 per day. Of the 6,739 machinists, blacksmiths, carpenters, and other mechanics employed, 4,404, or 65.4 per cent, were paid from $2 to $2.74 per day. The miners constituted 67.4 per cent of all employees; the largest number in any rate group appear to have received from $2 to $2.24. But on account of the mining being done on a tonnage basis the daily rates of pay are largely estimates and averages. There was paid as wages for the mining of bituminous coal on a tonnage basis the sum of $128,055,854. The daily rates of pay to miners' helpers show a distribution over a much wider range than is the case with other occupations. Of the timbermen and track layers 5,220, or 66.6 per cent, were paid at rates ranging from $2 to $2.49, and 90.3 per cent received from $1.50 to $2.74 per day. The 5,628 boys under 16 years of age constituted 2 per cent of all employees; 74 per cent received from $0.75 to $1.24 per day. The remaining wage-earners, classified as "all others," comprised 60,625, and constituted 21.6 per cent of all wage-earners, and 77.5 per cent of the number were paid at daily rates ranging from $1.50 to $2.49.

As shown in Table 60 the largest number of men, for the industry as a whole, was employed in December and the smallest number in July, the maximum and minimum numbers being only about 7 per cent above and below the average number. Michigan showed a heavy falling off from April to August, but as a rule the states do not show any wide fluctuations.

Contract work.—The expenditure for contract work amounted to $1,244,114, and 5,040 men were employed thereon. This was for tunneling, shaft sinking, and like work done under contract.

Supplies, materials, and miscellaneous expenses.—The cost of supplies and materials reported amounted to $24,798,922, or 10.4 per cent of all expenses, and was the largest item next to the amount paid for salaries and wages. The amount expended for miscellaneous expenses, $16,774,459, comprised $7,442,089 for royalties and rent of mine and mining plant, and $9,332,370 paid for rent of offices, taxes, and other sundries. Miscellaneous expenses formed 7 per cent of all expenses.

Production by states.—In the following table is shown the total production of bituminous coal by states during 1902, the distribution of the product for consumption, and the value and average price per ton at the mines.

TABLE 16.—COAL, BITUMINOUS—PRODUCTION, BY STATES AND TERRITORIES: 1902.

STATE OR TERRITORY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.

The following is a review of the production of bituminous coal in the several states and territories:

Alabama.—The coal fields of Alabama belong to the great Appalachian system, which extends from the northern part of Pennsylvania to the central part of Alabama. The coal bearing formations which become quite narrow in passing through Tennessee widen out suddenly in the northern part of Alabama and cover about 50 per cent of the northern half of the state.

The total coal area of Alabama is estimated at 6,500 square miles. There are 19 counties, all north of a line drawn midway across the state from east to west, which are underlaid by coal. In only 11 of these, however, is coal produced at present on a commercial scale. These 11 counties are Bibb, Blount, Cullman, Etowah, Jefferson, Marion, St. Clair, Shelby, Tuscaloosa, Walker, and Winston. The coal producing region is divided into 3 distinct basins or districts, which are known by the names of the rivers which drain them, the Black Warrior, the Coosa, and the Cahaba. The Warrior district is the largest, but the Cahaba is the principal producer, the county of Jefferson, which includes the city of Birmingham, in the Cahaba district, contributing more than 50 per cent of the state's total output.

All of the coals of the state are classed among the bituminous varieties. Some are coking coals of good quality, and to these is due the rapid growth of the iron and steel industries of the state. The development of these industries and of coal mining in Alabama during the last quarter of a century has been one of unusual rapidity.

The census of 1840 reported a production of coal in Alabama for that year, of 946 tons, and at the census of 1860, 10,200 tons were reported.

The distribution of the coal production, by counties, in 1902, is shown in the following table:

TABLE 17.—*Coal production of Alabama, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.
Total	7,271,146	78,903	244,223	2,760,298	10,354,570	$12,419,666	$1.20
Bibb	1,372,745	1,922	38,174	74,566	1,487,407	1,842,163	1.24
Etowah	100,290	1,280	220	.....	101,790	125,190	1.23
Jefferson	3,410,698	56,050	160,873	2,227,915	5,855,536	6,975,929	1.19
St. Clair	119,618	550	7,500	28,575	156,243	208,162	1.33
Shelby	131,241	130	4,672	.....	136,043	218,971	1.61
Tuscaloosa	108,617	924	1,848	320,322	431,711	527,504	1.22
Walker	1,748,073	16,047	30,936	108,920	1,903,976	2,147,894	1.13
Winston	26,686	2,000	.....	.....	28,686	41,250	1.44
Blount, Cullman, and Marion	253,178	.....	.....	.....	253,178	332,603	1.31

According to the Census report of 1870, the production for that year was 13,200 short tons. The output did not reach 100,000 tons until 1876, but in 1880, according to the Tenth Census, it had increased to 323,972 tons. From 1882 to 1885 there was a rapid increase in production, until at the height of the Birmingham boom, in 1885, it reached a total of 2,492,000 short tons.[1] With the bursting of the bubble and the temporary collapse of the boom, production fell off to less than 2,000,000 tons in 1886 and 1887, but as trade conditions became settled the coal mining industry improved and since 1888 has shown an almost continual growth in production. At the Eleventh Census, in 1889, the production amounted to 3,572,983 tons, about

[1] United States Geological Survey, "Mineral Resources of the United States," 1902, page 353.

eleven times what it was in 1880. In 1902 it reached the maximum, the output being 10,354,570 short tons. The selling value of this product at the mines was $12,419,666.

The amount paid in wages in 1902 was $7,841,457, salaries amounted to $709,449, contract work cost $265,579, miscellaneous expenses amounted to $734,972, and $1,219,310 was expended in the purchase of supplies and materials.

A summary of the statistics, by counties, is given in the following table, only those counties being reported separately which produce a total of 200,000 tons:

TABLE 18.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

COUNTY.	Number of mines.	Number of operators.	SALARIED OFFICIALS, CLERKS, ETC.		WAGE-EARNERS.		CONTRACT WORK.		Miscellaneous expenses.	Cost of supplies and materials.	PRODUCT.	
			Number.	Salaries.	Average number.	Wages.	Amount paid.	Number of employees.			Quantity (short tons).	Value.

[1] Includes Blount, Cullman, Etowah, Marion, St. Clair, Shelby, and Winston.

Alaska.[1]—There are a number of localities in the territory of Alaska where coal seams of workable thickness and quality have been located, but it has been impossible to secure exact statistics in regard to the production. Mr. Alfred H. Brooks, of the United States Geological Survey, in his report entitled "The Coal Resources of Alaska,"[2] states that the coal mines of Alaska which have produced some coal in the past may be divided naturally into three separate provinces or districts—the Pacific coast district, the Yukon district, and the Arctic coast district. The Pacific coast district includes all the mines located on Pacific coast waters and one deposit at Kootznahoo bay, one at Controller bay, one at Homer (on Cook inlet), and three on the Alaskan peninsula—at Chignik river, Herendeen bay, and Unga Island. The Yukon district includes all the mines on or near the Yukon river. Of these there are six, three of which—known, respectively, as No. 1, Williams, and Blatchford—are on the Yukon river, between Anvik and Nulato; the Pickart mine is located a short distance northeast of Nulato, on the Yukon river; the Drew mine near Rampart; and Nation River mine, between Fort Yukon and Fortymile. The Arctic coast district includes two mines, the Corwin and the Thetis, located on the Arctic ocean near the seventieth degree of north latitude. Mr. Brooks states that at the time of his visit to the region, in 1902, the mine on Kootznahoo bay, the only one in southeastern Alaska, had been shut down. He also reports that at Controller bay, 30 miles east of the mouth of the Copper river, an excellent coal has been discovered, and extensive preparations are under way for developing the field. It is probable that this mine will become a producer within a short time.

The only mines in American territory from which any production was reported for 1902 were the Williams mine, on the Yukon river below Kaltag, and the Homer property, on Cook inlet. The first mentioned property produced, in 1902, 1,700 tons of coal, which was used principally on the steamers plying on the Yukon river. The Pickart mine, also on the Yukon river, was operated for a short time during 1902, but was closed down in July. No exact information as to the amount of coal obtained during this time has been secured. The Homer mine, on Cook inlet, produced 512 tons, most of which was obtained in the course of the development of the property. At this point a railway about 7 miles in length connects the mine with the navigable waters of Cook inlet, where docks and coal bunkers have been established. The three mines on the Alaskan peninsula have been operated at different times during the last two decades, but no production was reported from them in 1902, although the one on Chignik river is known to have produced some coal to supply the local steamers, and the same is true of the one on Unga Island. A company was organized during 1902 to extend the developments of the mines on Herendeen bay, but no production was reported from it during the year. The two mines in the Arctic coast district have been worked from time to time during the last twenty years to supply whalers and revenue cutters, but the operations have never reached the dignity of an industry, and no record of their actual production has been secured. Some attempt, however, at systematic development has been recently made, and a small amount of coal was shipped to Nome, where it was said to have brought a good price.

[1] United States Geological Survey, "Mineral Resources of the United States," 1902.

[2] Twenty-second Annual Report of the United States Geological Survey, Part III.

Mr. Arthur J. Collier, assistant geologist, United States Geological Survey, who made a special investigation of the coal resources of the Yukon, has published his results in Bulletin No. 218.

During the field season of 1902 Mr. Collier was able to secure more definite data in regard to the production of the different mines along the Yukon river than have heretofore been obtained. He states that the Williams mine, on the Yukon river, 50 miles below Kaltag, which was first known as the Thein mine, was the only mine in American territory on the Yukon which was worked continuously during the season of 1902. This mine was opened in 1900 and produced some coal in that year.

The Pickart mine, 10 miles above Nulato, was opened in 1898, and produced some coal each year from that time until 1902, when it was abandoned. No definite statement as to the amount of coal produced during this time has been obtained, but the output was probably between 2,000 and 3,000 tons. The first mine to be opened on the Yukon river was what is known as the Nation River mine, 52 miles below the international boundary. About 2,000 tons of coal are said to have been produced from this mine in 1897; the mine has since been shut down and is not now operated. The next mine to be opened was what is known as the Drew mine, about 25 miles above Rampart. This mine was worked from 1897 to 1900, during which time the entire production is estimated to have amounted to about 1,200 tons. The Blatchford mine, 9 miles below Nulato, was opened in 1898 and produced some coal in 1899, 1900, and 1901. It is estimated that about 300 tons were produced at this mine during these years. What is known as Mine No. 1, about 25 miles below the Williams mine, was worked during the winter of 1898, and produced about 900 tons. Since that time it has been shut down. Mr. Collier estimates that the total amount of coal produced in American territory on the Yukon from 1897 to 1902, inclusive, is about 9,000 tons—this total being distributed annually approximately as follows:

Production of coal on the Yukon river: 1897 to 1902.

YEAR.	Name of mine.	Quantity (short tons).	Value.
1897	Nation River	2,000	$28,000
1898	No. 1, Drew, and Pickart	1,600	22,400
1899	Drew, Pickart, and Blatchford	1,200	16,800
1900	Drew, Pickart, Blatchford, and Thein	1,200	16,800
1901	Pickart, Blatchford, and Thein	1,300	15,600
1902	Williams	1,700	17,000

All of these mines are located immediately on the Yukon river. The coal from them has been used principally on the river steamers, though a smaller amount has been used for domestic purposes at Dawson and other points along the river. At Dawson the coal sells at from $15 to $20 per ton. Coal delivered at the river banks from the Yukon mines sells for from $10 to $12 per ton at present, though in years past prices have been higher, and in 1900 coal was selling for $15 per ton at the Drew mine. Adding the production of the Cook inlet mine to that of the Williams mine in 1902, the total production reported for the territory is found to be 2,212 tons, valued at $19,048. It is known, however, that some coal was also produced at the Corwin mine, at Chignik, and at Herendeen bay, but since no definite reports have been obtained from these localities they are not included in the above statement. The actual production in the territory for 1902 was, therefore, probably somewhat larger than that reported.

Arkansas.—According to Mr. Joseph A. Taff, of the United States Geological Survey, the Arkansas coal field is a direct continuation of the Indian Territory coal field, and extends from the western line of the state in an easterly direction about 75 miles. It follows the valley of the Arkansas river, which passes from west to east about the middle of the main basin.

The north edge of the field lies upon the southern foothills of the Boston mountains, which form the southern limit of the Ozark uplift. The southern border of the field is near the Ouachita mountain ridges, which extend from the vicinity of Little Rock westward into Indian Territory.

The coals vary from bituminous to semianthracite, the latter having a high reputation as a smokeless domestic fuel, its smokeless qualities causing it to be received with great favor in the cities of the Mississippi valley. It burns with a short, hot flame and leaves a comparatively small amount of ash.

The census of 1860 reported the production of 200 tons of coal for Arkansas, but the reports of the Ninth Census contained no account of production for this state. The production for 1880 was small, 14,778 short tons, having a value of $33,535. The wages paid amounted to $20,850. In 1889, at the taking of the Eleventh Census, the production amounted to 279,584 short tons, valued at $395,836. In 1902 the production had grown to 1,943,932 short tons, valued at $2,539,214.

The statistics of production in 1902, by counties, are given in the following table:

TABLE 19.—*Coal production of Arkansas, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Total quantity (short tons).	Total value.	Average price per ton.
Total	1,864,912	13,639	65,381	1,943,932	$2,539,214	$1.31
Franklin	327,418	1,199	9,396	338,013	377,794	1.12
Johnson	186,812	1,072	5,374	193,258	404,822	2.09
Logan	19,286	1,215	1,250	21,751	36,000	1.66
Pope	29,389	500	5,077	34,966	101,474	2.90
Sebastian	1,275,324	6,053	43,804	1,325,181	1,583,209	1.19
Ouachita and Scott	26,683	3,600	480	30,763	35,915	1.17

In the following table is presented a summary of the statistics in connection with the coal production of Arkansas:

TABLE 20.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

COUNTY.	Number of mines.	Number of operators.	SALARIED OFFICIALS, CLERKS, ETC.		WAGE-EARNERS.		CONTRACT WORK.		Miscellaneous expenses.	Cost of supplies and materials.	PRODUCT.	
			Number.	Salaries.	Average number.	Wages.	Amount paid.	Number of employees.			Quantity (short tons).	Value.
Total	53	33	146	$148,113	2,574	$1,780,061	$485	5	$82,949	$177,716	1,943,932	$2,539,214
Sebastian	27	14	84	98,371	1,650	1,180,617	485	5	64,342	128,486	1,325,181	1,583,209
Other counties[1]	26	19	62	49,742	924	599,444			18,607	49,230	618,751	956,005

[1] Includes Franklin, Johnson, Logan, Ouachita, Pope, and Scott. (Franklin county had a production exceeding 200,000 tons, but is not shown separately in order to avoid disclosing the operations of individual operators.)

California.—All of the coal mined in both California and Oregon is of the lignite variety. In California there are a number of rather widely separated fields, the chief of which are the Mt. Diablo and Corral Hollow. The principal production in 1902 was from Alameda and Contra Costa counties, the former producing about 80 per cent of the state's total output. Smaller amounts were mined in Kern, Monterey, Riverside, and Siskiyou counties. In a number of other counties coal veins have been prospected, and the counties of Amador, Butte, Del Norte, Fresno, Orange, and San Diego have produced some lignite coal in the past. These mines, however, have been abandoned from one cause or another, principally the quality of the coal, although there was also difficulty in the mining. The Corral Hollow field, which is the one in Alameda county, has a considerable advantage, on account of its proximity to San Francisco, where the product finds its principal market. The total production of lignite in California during 1902 was only 84,984 short tons, as compared with 119,820 short tons in 1889.

The comparatively small coal mining industry of California is subjected to influences which do not affect other states. One of these is the exportation of wheat from the Pacific seaports. Vessels carrying wheat as an outgoing cargo are apt to bring back, at a low rate of freight, coals from Australia or Japan. When such is the case the demand for California coal falls off. In the years 1899, 1900, and 1901, according to the reports of the United States Geological Survey, occurred the largest outputs of coal in the state of California since 1880. The production in 1902 was reduced much below that of these years on account of the large production of crude petroleum, the use of which for fuel purposes in the manufacturing industries of the state developed very rapidly in 1902.

Colorado.—The coal fields of Colorado have been fully described by Mr. R. C. Hills, in Mineral Resources of the United States, 1892. They have also been described in considerable detail by Mr. L. S. Storrs in the Twenty-second Annual Report of the United States Geological Survey, Part III. Geologically, the coal bearing rocks of Colorado are confined to the Upper Cretaceous coal measures and, with only few exceptions, to the Laramie formation in these measures. The coal bearing territory is found along both the eastern and western flanks of the Rocky mountains.

The coal producing areas are divided into 3 groups, the Eastern, Park, and Western, the fields of each group being separated by areas of great elevation and erosion. The groups are again subdivided into distinct fields, as follows: The Eastern group into the Raton, Canyon City, and South Platte; the Park group into the Middle Park and Como; and the Western group into the Yampa, Grand river, and La Plata.

The coal fields of Colorado contain every variety of coal, from the typical lignite to the true anthracite. The area of the latter, however, is very small, Mr. Storrs stating that it probably does not exceed 80 square miles.

Owing to the aggressive policy of the Colorado Fuel and Iron Company, the coal fields of Colorado have been more thoroughly explored than those of any other state in the Rocky mountain region. Mr. Hills, in his report on Mineral Resources of the United States, 1892, estimates the available gross tonnage of the Colorado fields at 45,197,100,000 short tons, and estimating 75 per cent of this as recoverable, the net available supply is placed at 33,897,800,000 tons.

The production of the state in 1902, by counties, with the distribution of the product for consumption, was as follows:

TABLE 21.—*Coal production of Colorado, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.
Total	5,375,215	282,027	181,546	1,562,555	7,401,343	$8,397,812	$1.13

[1] Includes Arapahoe, Larimer, Mesa, Montezuma, Ouray, Pitkin, and Rio Blanco.

Coal mining operations, as far as known, began in Colorado in 1864, the production in that year amounting to 500 tons. In 1870 the amount produced was 5,040 short tons, and at the taking of the Tenth Census the production amounted to 462,747 tons. In 1889 it had increased to 2,544,144 tons, and in 1902 it amounted to 7,401,343 tons. The United States Geological Survey estimates that the total amount of coal produced in Colorado from 1864 to the close of 1902 was 68,842,054 tons, or about one-fifth of 1 per cent of the net available supply estimated by Mr. Hills.

During 1902 coal was produced in Colorado in 18 counties, but in 7 of these there were not more than 2 establishments, so that the statistics of these 7 have been combined.

The following table is a summary of the statistics by counties where the production was 200,000 short tons:

TABLE 22.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

COUNTY.	Number of mines.	Number of operators.	SALARIED OFFICIALS, CLERKS, ETC.		WAGE-EARNERS.		CONTRACT WORK.		Miscellaneous expenses.	Cost of supplies and materials.	PRODUCT.	
			Number.	Salaries.	Average number.	Wages.	Amount paid.	Number of employees.			Quantity (short tons).	Value.

[1] Includes Arapahoe, Delta, La Plata, Larimer, Mesa, Montezuma, Ouray, Pitkin, Rio Blanco, Routt, and Weld. (Pitkin county had a production exceeding 200,000 tons, but is not shown separately in order to avoid disclosing the operations of individual operators.)

Illinois.—The coal fields of Illinois form by far the greater portion of the great Central coal field which underlies the larger part of Illinois, the southwestern part of Indiana, and several counties of western Kentucky.

Nearly three-fourths of the state of Illinois is underlaid by productive coal measures, the entire area being estimated at 42,900 square miles. This is the largest coal bearing area recorded for any state of the Union. There are more counties in this state in which coal is produced than in any other of the United States, the production in 1902 being reported from 54 different counties. In 9 of these the production exceeded 1,000,000 tons, and in 9 more the production was between 500,000 and 1,000,000 tons. The coal is principally bituminous, of the dry, noncoking variety.

In 1902 the state was the second in importance among the coal producing states, being outranked only by Pennsylvania. Its production was 10.9 per cent of the total production of the United States; the value was 9.2 per cent of the total value. The output in 1902 amounted to 32,939,373 short tons, valued at $33,945,910. At the taking of the Eleventh Census the production of coal in Illinois was 12,104,272 short tons, worth at the mines $11,755,203. The total production of the state during the census year 1880 was 6,115,377 short tons, valued at $8,779,832.

The expenditures reported were: For salaries, $1,564,832; for wages, $24,876,201; for contract work, $24,699; for miscellaneous expenses, $1,258,686; and for supplies and materials, $2,834,444. The incorporated companies paid $680,488 in dividends on capital stock, and $210,556 in interest on bonds.

The production by counties and the disposition of the product are shown in Table 23.

TABLE 23.—*Coal production of Illinois, by counties: 1902.*

[1] Includes Bond, Brown, Calhoun, Cass, Edwards, Gallatin, Greene, Hamilton, Hancock, Henry, Jefferson, Jersey, Johnson, Kankakee, Knox, McDonough, McLean, Macon, Morgan, Rock Island, Schuyler, Scott, Shelby, Stork, Tazewell, Wabash, Warren, Washington, Will, and Woodford.

Indian Territory.—The coal areas of Indian Territory form a portion of the Western coal field, and are directly connected with the coal fields of Kansas on the north and those of Arkansas on the east.

The greater portion of the development has been in the Choctaw nation, in the territory tributary to the Missouri, Kansas and Texas Railway and the St. Louis and San Francisco Railroad, which cross the territory from north to south, and to the Choctaw, Oklahoma and Gulf Railroad, crossing it from east to west. Workable areas also underlie about half of the Cherokee nation, all of the Creek nation, and the northeast corner of the Chickasaw nation. The area underlaid by workable seams is estimated to contain about 14,848 square miles.

The entire production in the territory was from the Cherokee and Choctaw nations, the latter contributing by far the larger portion. The first recorded production was in 1880, when the amount was reported as 120,947 short tons. By the time the Eleventh Census was taken this production had increased to 752,832 tons, or 50 per cent; in 1902 it had grown to 2,820,666 tons. Of the amount of coal produced during 1902, 2,587,100 tons were loaded at mines for shipment; 25,998 tons were sold to the local trade and used by employees; 96,017 tons were used at the mines for steam and heat, and 111,551 tons were made into coke. The average price per ton received for coal was $1.51, as compared with $1.76 in 1889.

Indiana.—The coal fields of Indiana underlie the counties in the southwestern portion of the state and form a portion of the large Central coal field. There are said to be at least 8 workable coal beds, although as a usual thing not more than 3 of these are found in workable thickness at any one locality, and generally there is only one bed that can be worked from one shaft.

The eastern part of the coal fields of Indiana is noted for its production of what is known as Indiana, or "Brazil" block coal, which is in favor as a domestic and steam fuel. This coal receives its name from the almost perfect rectangular blocks into which the coal naturally breaks because of the pronounced cleavage planes intersecting each other at right angles. Some cannel and some semiblock coal are also produced in this state.

The production in 1902 amounted to 9,446,424 short tons, valued at $10,399,660. In 1889 the production was reported by the Eleventh Census at 2,845,057 short tons, valued at $2,887,852, and the Tenth Census in 1880 reported the production of that year at 1,454,327 short tons, valued at $2,150,258.

Table 25 shows by counties the total production of Indiana in 1902, the disposition of the same, and the total amount received for the coal sold, together with the average price per ton at the mines.

TABLE 25.—*Coal production of Indiana, by counties: 1902.*

The production of Indiana in 1902 included 1,101,544 short tons of block and semiblock coal, 1,000 tons of splint coal, and 30,000 tons of cannel coal. The remainder of the product was noncoking bituminous coal. The reported mining expenses incurred in the production of Indiana coal in 1902 were as follows: For salaries, $530,492; for wages, $7,396,425; for contract work, $26,603; miscellaneous expenses, $449,054; and for supplies and materials, $729,104. The dividends paid by incorporated companies amounted during the year to $161,336, the interest paid on bonds to $16,720, and assessments were levied to the amount of $83,700. The statistics of mining operations during 1902, in counties having a production of 200,000 tons and over, are as follows:

TABLE 26.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

[1] Includes Dubois, Fountain, Gibson, Knox, Martin, Perry, Spencer, and Warren.

Iowa.—The northern part of the Western coal field is in the southwestern portion of Iowa, about two-fifths of the state being underlaid by coal, which is mined in 24 counties; 4 of these, namely, Appanoose, Mahaska, Monroe, and Polk, produced about two-thirds of the total. The total coal producing area is estimated at 20,000 square miles. The product is of the dry noncoking variety of bituminous coal, with small amounts of block and cannel. With the exception of the block and cannel coals, the product is generally better adapted for steam raising than for any other industrial purpose. Some attempts have been made to coke the Iowa coals on a commercial basis, but owing to the competition of the higher grade product from other sources the attempts were not profitable and have been abandoned, and no coke has been made in Iowa since 1891, in which year 157 tons were produced. The coals are usually high in both sulphur and ash.

Coal mining in Iowa began at quite an early date, an output of 360 tons having been reported as early as 1840. The Eighth Census showed that the production for 1860 was 41,920 short tons. By 1870 it had grown to 263,487 tons, and in 1880 to 1,461,116 tons. The census of 1889 showed a production of 4,095,358 tons. By 1902 it amounted to 5,904,766 tons. In amount of production Iowa ranked ninth among the coal producing states; in the states west of the Mississippi river it stood second, Colorado being first.

The following table shows the production, distribution, and price of coal in Iowa by counties during 1902:

TABLE 27.—*Coal production of Iowa, by counties: 1902.*

[1] Includes Adams, Dallas, Davis, Greene, Guthrie, Jefferson, Keokuk, Lucas, Page, Scott, Story, Taylor, Van Buren, Warren, Wayne, and Webster. (Lucas county had a production exceeding 200,000 tons, but is not shown separately in order to avoid disclosing the operations of individual operators.)

Kansas.—The Kansas coal areas lie entirely in the eastern portion of the state, the western boundary of the Western coal field traversing Kansas in an almost due north and south line from Marshall county, adjoining the state line of Nebraska on the north, to Chautauqua county, adjoining Indian Territory on the south. There are some isolated deposits in the central portion of the state, but the beds are thin and the coal is of inferior quality and not at present mined on a commercial scale. The larger portion of the production is obtained from the counties of Cherokee and Crawford, in the southeastern corner of the state, these 2 counties contributing about 90 per cent of the entire output. These 2 counties are underlaid by the Lower Coal Measures, which form the eastern portion of the Western field, and which contain the most important and productive beds.

The production of the state is used principally for domestic and railroad consumption. A small quantity of coke is made at irregular intervals in Cherokee county, the coke being utilized by the zinc smelters in the immediate vicinity. The larger portion of the product is, like that of Iowa, of the dry, noncoking variety of bituminous coal.

Coal mining as an industry in Kansas, so far as records are concerned, began in 1869, when, according to the report of the United States Geological Survey, 36,891 tons were produced. In 1880, at the taking of the Tenth Census, the production of coal in Kansas amounted to 771,442 short tons. In 1889 it had increased to 2,221,043 tons. In 1902 it amounted to 5,266,065 tons. The development of the coal mining industry in Kansas, as in the adjoining states, Iowa and Missouri, has kept pace with the increase of population and the establishment of manufacturing industries. The markets are restricted to a comparatively limited area, and the coal is not shipped to points far distant from the mines. Any increase in production from this part of the Western coal field may be accepted as indicative in large part of the development and growth of population and manufactures within the 3 states. The statistics of production for 1902 are as follows:

TABLE 29.—*Coal production of Kansas, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.
Total	4,941,236	227,826	95,237	1,766	5,266,065	$6,862,787	$1.30

[1] Includes Atchison, Bourbon, Coffey, Jewell, Labette, and Republic.

There are only 3 counties in the state the production of which in 1902 exceeded 200,000 tons. These counties were Cherokee, Crawford, and Leavenworth. The statistics of salaries, wages, and other expenses in these counties, as compared with the production and value, are shown in Table 30.

TABLE 30.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

Kentucky.—Kentucky is the only one of the United States whose coal product is drawn from more than one of the great coal fields. The coal producing counties of the eastern portion of the state are included in the coal measures of the Appalachian system, while the southern extremity of the Western coal field is found in the western counties. More than half of the entire production is obtained from the counties in the western part of the state. The Appalachian system covers the entire eastern portion of the state to an extent of 10,300 square miles, and the portion of the western part of the state underlaid by coal is estimated to contain 5,800 square miles, making a total area of 16,100 square miles.

The principal producing counties in the eastern portion of the state are: Bell, Boyd, Breathitt, Carter, Greenup, Johnson, Knox, Laurel, Lawrence, Lee, Pulaski, Rockcastle, and Whitley.

Those in the western portion are: Butler, Christian, Daviess, Hancock, Henderson, Hopkins, McLean, Muhlenberg, Ohio, Union, and Webster.

The coal found in the eastern portion of the state is usually the semibituminous variety, free burning and noncoking, but the different seams comprise all varieties of bituminous coal, from bituminous shale to cannel coal. Some of the coals in the eastern portion of the state have a high reputation as steam producers, particularly that kind known as the Jellico coal, which is mined in Whitley county, Kentucky, and in Campbell county, Tennessee. A considerable quantity of coke is made from coal mined in Hopkins county in the Western coal field, and in Bell county in the southern portion of the Eastern district. The state possesses some of the finest beds of cannel coal known to exist in the United States. It is mined both in the eastern and western districts, and is distributed widely throughout the eastern cities as a domestic grate coal. This cannel coal commands a much higher price at the mine than the ordinary bituminous and semibituminous coal mined in the state.

The production of cannel coal in Kentucky in 1902 amounted to 65,317 short tons, the largest output of this variety of coal obtained in any of the producing states. The census of 1840 credits Kentucky with a production of 23,527 short tons, and at the census of 1860, 285,760 tons were reported. The census of 1870 shows that Kentucky produced in that year 168,651 short tons, and at the census of 1880 the production was 946,288 short tons; in 1889 the Eleventh Census reported a production of 2,399,755 tons. In 1902 the output amounted to 6,766,984 tons. The production has increased steadily since 1893, the output in 1902 being more than double that in the former year.

Kentucky ranked eighth in importance among the coal producing states in 1902, and third among those south of the Ohio and Potomac rivers.

The production by counties, with the distribution of the product for consumption, is shown for Kentucky in Table 31.

TABLE 31.—COAL PRODUCTION OF KENTUCKY, BY COUNTIES: 1902.

Hopkins county is the most important producer, having an output in 1902 of 1,555,084 short tons. The largest mines in the state are located in this county.

Table 32 shows the statistics relating to coal mining in Kentucky for such counties as produced 200,000 tons or over during 1902. It should be stated here that the statistics do not include a large number (from 1,000 to 1,200) of small country banks producing anywhere from 5 to 50 tons of coal a year, reports from which could not be obtained by correspondence. The quantity and value of the product were not sufficient to warrant the expense necessary to secure the reports by personal visits of special agents.

TABLE 32.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

[1] Includes Breathitt, Butler, Christian, Clay, Crittenden, Daviess, Edmonson, Elliott, Floyd, Grayson, Greenup, Hancock, Harlan, Henderson, Jackson, Johnson, Knott, Lawrence, Lee, Leslie, Letcher, McLean, Madison, Magoffin, Martin, Menifee, Morgan, Owsley, Perry, Pike, Pulaski, Rockcastle, Trigg, Warren, Wayne, and Wolfe.

Maryland.—The coal fields of Maryland are a part of an extensive basin extending from Somerset county, in Pennsylvania, through Allegany and Garrett counties, in the western part of Maryland, to Tucker county, in West Virginia. They are separated from the main field of the Appalachian system by the Great Savage mountains, and are nearer to tidewater than any of the important coal producing fields of the United States.

In this region there occurs what is known as the Big Vein of Maryland and West Virginia, the production from which has a high and thoroughly established reputation for quality. As a blacksmithing coal it stands without a competitor in the United States, to almost all portions of which it is shipped for this purpose. Some Maryland coal is also sent abroad for blacksmithing and forge purposes. This coal is also said to make good coke, but on account of the high price obtained for the raw coal it is found more profitable to sell it in that condition than to make it into coke. Practically the entire product is sold as run-of-mine, and little screening is done in preparing the coal for market.

The first discovery of coal in Maryland was made in the vicinity of Frostburg in 1804, and coal has been extracted from this section almost continuously since that date. The exploitation on a commercial basis may be said to have begun with the construction of the Baltimore and Ohio Railroad, which reached the coal fields in 1842. According to the reports of the "Cumberland Coal Trade," which have been kept continuously since that date, shipments in 1842 amounted to 1,913 short tons, and adding an estimate of 10 per cent for local consumption, the production in that year would have been 2,104 tons. In 1850 the Chesapeake and Ohio Canal was completed to Cumberland, and from that date the production of the region continued to grow rapidly, although on account of the comparatively small productive area the increase in production has not kept pace with that of some of the other states having larger coal areas. It is thought that the maximum yearly production for Maryland has been nearly reached. The output in 1902 amounted to 5,271,609 short tons, valued at $5,579,869, as compared with 2,939,715 short tons, valued at $2,517,474, in 1889, and 2,228,917 short tons, valued at $2,585,537, in 1880. The product of 1902 was distributed as follows:

	Tons.
Loaded at mines for shipment	5,187,175
Sold to local trade and used by employees	48,631
Used at mines for steam and heat	35,803

The coal mining industry of Maryland in 1902 was considerably benefited through the strike in the anthracite coal fields in Pennsylvania. The average price per short ton was $1.06 in 1902, as compared with $0.99 in 1901. In 1889 the average price per short ton was $0.86. The bulk of the production was from Allegany county, only 2.7 per cent of the output in 1902 being from Garrett county.

Michigan.—All of what is known as the Northern coal field lies within the lower peninsula of the state of Michigan, between Lake Michigan and Lake Huron. It is estimated to contain an area of approximately 11,300 square miles. It is the only coal field known in the drainage basin of the Great Lakes and the St. Lawrence river. The coal is of an inferior quality, when compared with that of the Appalachian region, having a high percentage of both ash and sulphur. It is probably for this reason that the development of the region has been somewhat slow in comparison with that of other regions.

It is reported that the portion of the field near Jackson was producing coal as early as 1835, but it was not until 1868 that any estimate of the production was obtained. In that year the output amounted, it is stated, to 28,000 tons. The Census report of 1870 gave the production at 31,528 short tons. In 1880, according to the Tenth Census, the production was 100,800 short tons. In 1881 and 1882 there was a little increase, but for the next thirteen years, according to the reports of the United States Geological Survey, the production not only did not increase, but showed a declining tendency, which was due undoubtedly to the excessive production and consequent low prices of coal from the fields having a better quality or lower cost of production. At the Eleventh Census, for the year 1889, the output was only 67,431 tons. Since 1897, however, because of the higher prices of coal from other regions, and also because of the rapid industrial growth of the cities on Lake Erie and Lake Huron, the demand for, and the production of, Michigan coal have increased with notable rapidity. According to the report of the United States Geological Survey the production of coal in Michigan in 1901 was 1,241,241 short tons. A strike of the mine workers in 1902 reduced the production of the state to 964,718 short tons.

The distribution of this production, by counties, is shown in the following table:

TABLE 33.—*Coal production of Michigan, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at the mines for steam and heat (short tons).	Total quantity (short tons).	Total value.	Average price per ton.
Total	818,687	117,978	28,053	964,718	$1,653,192	$1.71
Bay	209,133	29,596	9,916	248,645	410,615	1.65

Saginaw	604,904	50,100	15,300	670,304	1,141,409	1.70
Huron, Jackson, and Shiawassee	4,650	30,301	2,738	37,689	82,278	2.18

There were only two counties the production of which exceeded 200,000 tons during the year. The following table shows the statistics of coal mining for these counties for 1902:

TABLE 34.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

COUNTY.	Number of mines.	Number of operators.	SALARIED OFFICIALS, CLERKS, ETC.		WAGE-EARNERS.		CONTRACT WORK.		Miscellaneous expenses.	Cost of supplies and materials.	PRODUCT.

[1] Includes Eaton, Huron, Jackson, and Shiawassee.

Missouri.—The coal areas of Missouri belong to the Western coal field and underlie about one-half of the state, the dividing line being one roughly drawn from the northeastern to the southwestern corners of the state. As they belong to the same field as those of Iowa and Kansas, what has been said in regard to the nature of the coals of those states applies also to the coals of Missouri.

Practically all of the coal produced in the state is consumed within its borders, and, other things being equal, any increased production may be considered as probably indicating a growth in local population or industry. The state is almost entirely surrounded by other coal producing states, and the large cities of the eastern portion obtain their principal supply of fuel from Illinois rather than from the mines of Missouri.

As far as any historical records go, the development of the coal mines of Missouri began in the same year as coal mining in Iowa. This was in 1840, when an output of 9,971 tons was obtained. At the census of 1870 the product was reported as 621,930 tons and at the census of 1880, as 844,304 tons. The Eleventh Census shows the production in 1889 to have been 2,557,823 tons, while in 1902 it amounted to 3,890,154 tons. Owing to the natural restrictions upon the marketing of Missouri coal, its increase in production has not kept pace with that of the neighboring states.

In Table 35 is shown the production of coal in 1902, by counties, with the distribution of the product for consumption.

TABLE 35.—*Coal production of Missouri, by counties: 1902.*

There were 33 counties in the state from which coal production was reported in 1902, although coal is found in as many as 39 counties. Of the 33 counties producing in 1902, there were 8 in which the output exceeded 200,000 tons.

The statistics for the industry are shown in the following table, the counties producing over 200,000 tons being given separately:

TABLE 36.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

COUNTY.	Number of mines.	Number of operators.	SALARIED OFFICIALS, CLERKS, ETC.		WAGE-EARNERS.		CONTRACT WORK.		Miscellaneous expenses.	Cost of supplies and materials.	PRODUCT.

[1] Not reported.
[2] Includes Audrain, Boone, Caldwell, Callaway, Carroll, Cedar, Chariton, Cooper, Dade, Grundy, Henry, Howard, Jackson, Johnson, Linn, Livingston, Monroe, Montgomery, Morgan, Pettis, Putnam, Ralls, St. Clair, Saline, and Schuyler.

Montana.—The coal areas of Montana are included in the Rocky Mountain fields. Most of the deposits are of the Cretaceous age and vary from lignite to bituminous, the lignites usually being in the plains region and the bituminous coals in the mountain ranges. The coal fields form a nearly continuous belt, and cross the state in a northwest-southeast direction. Little detailed investigation has been made and only a general idea can be formed as to the extent and value of these fields. The coal bearing areas are estimated to contain 32,000 square miles. Some of the coals possess excellent coking qualities, the coke being used in the smelters and refineries as far east as Omaha.

The first statement regarding the production of coal in Montana is that made by the Tenth Census, which shows that in 1880, 224 tons were produced. The active development of Montana's coal mines began in the latter part of the decade 1880 to 1890, and in 1889, according to the Eleventh Census, the production was 363,301 short tons, valued at $880,773, or an average of $2.42 per ton. In 1902 the production was 1,560,823 short tons, worth $2,443,447, or an average of $1.57 per ton. According to the reports of the United States Geological Survey the coal production of Montana reached the market limits in 1895, when it amounted to 1,504,193 short tons. Since that time the production has remained almost stationary, the maximum being attained in 1900, with a total of 1,661,775 short tons, and the minimum in 1901, when a total of 1,396,081 tons was produced.

The statistics of production in 1902, by counties, with the distribution of the product for consumption, are shown in the following table:

TABLE 37.—*Coal production of Montana, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at the mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.
Total	1,385,100	40,719	39,023	95,981	1,560,823	$2,443,447	$1.57
Carbon	576,472	9,270	19,212	.....	604,954	791,222	1.31
Cascade	697,883	14,050	14,398	35,241	761,572	1,274,169	1.67

Fergus	600	4,600	.....	.....	5,200	16,900	3.25
Park	23,660	1,470	3,770	60,740	89,640	189,080	2.11
Other counties[1]	86,225	817	1,643	.....	88,685	145,012	1.64

[1] Includes Deerlodge, Gallatin, Granite, and Meagher.

As shown in the above table there were only two counties, Carbon and Cascade, in which the production exceeded 200,000 short tons annually. These two counties together in 1902 produced 1,366,526 short tons out of a total of 1,560,823 short tons.

The statistics of the industry are given in the following table, the counties of Carbon and Cascade having a production of over 200,000 tons each, being shown separately:

TABLE 38.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

COUNTY.	Number of mines.	Number of operators.	SALARIED OFFICIALS, CLERKS, ETC.		WAGE-EARNERS.		CONTRACT WORK.		Miscellaneous expenses.	Cost of supplies and materials.	PRODUCT.

[1] Includes Choteau, Deerlodge, Fergus, Gallatin, Granite, Meagher, and Park.

New Mexico.—The coal producing areas of New Mexico are found in somewhat widely distributed fields or basins having seemingly little connection with each other. The three most important areas are those in Colfax, Rio Arriba, and McKinley counties. The first-mentioned area is an extension southward of the Las Animas, or Trinidad, area in Colorado, and occupies the northwestern portion of Colfax county. The La Plata field of Colorado, which is found in the southwestern portion of that state, suddenly turns at its eastern extremity and extends in a narrow strip almost due south, through Rio Arriba county and into McKinley county. Owing to its distance from railroad communication, this area has not been extensively developed. The Gallup field, which occupies a long, narrow strip extending north and south in the western part of McKinley county and into San Juan county on the north and Valencia county on the south, is one of the most extensively developed areas in the territory. In addition to these there are the Los Cerrillos area, in Santa Fe county, and the Carthage area, in Socorro county, in both of which mining operations are carried on. These are the only fields which have been extensively developed, although there are some isolated fields of economic importance in the territory, where small amounts are mined for local consumption.

The coals of New Mexico, like those of Colorado, range from lignite to anthracite. The anthracite occurs

in the Los Cerrillos field, which has been penetrated by volcanic intrusion in close proximity to the coal beds, with the result of altering the bituminous coal to an anthracite of good grade. This anthracite is sold as far north as Denver and as far west as San Francisco. In 1902 the production was 41,326 short tons. All of this anthracite occurs in the northern part of the field. Toward the south the coal passes into coking and semi-coking varieties of bituminous coal, the transition being very gradual and almost imperceptible. Good coking coal was also produced in Colfax county, the principal operations being near Raton. There were 8 counties in the territory which produced coal in 1902. In only 2, Colfax and McKinley, did the product amount to as much as 200,000 short tons during the year. No report of coal production in New Mexico was made at the Tenth Census, the first record of operations being that for the United States Geological Survey in 1882, in which year an output of 157,092 short tons was obtained. The production reported at the Eleventh Census, for 1889, was 486,463 tons. In 1902 it was 41,326 short tons of anthracite and 1,007,437 short tons of bituminous, a total production of 1,048,763 short tons.

In the following table is shown the production in 1902, by counties, with the distribution of the product for consumption:

TABLE 39.—*Coal production of New Mexico, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at the mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.

[1] Includes Lincoln, Rio Arriba, San Juan, Sante Fe, San Miguel, and Socorro.

North Carolina.—The only productive coal field in North Carolina is a small area lying in the valley of the Deep river, just west of the point where it joins the Cape Fear river. The area from which coal may be produced is a narrow strip 30 miles in length. Another small area lying along the Dan river, near where it crosses the Virginia line, is known to contain some coal, but it has not been developed and is regarded as of little promise for the future. The only mine operated in the Deep river basin is the Cumnock, formerly known as the Egypt mine. It was opened in 1889, with a production during that year of 192 tons. Detailed statistics are not published separately, in order that the confidential nature of the reports to the Bureau of the Census may be maintained.

North Dakota.—Although the coal producing areas of North Dakota are included in the Rocky Mountain fields they are not within the mountainous areas. They lie in about the middle of the state, in the great plains region.

All of the coal produced in the state is lignite and disintegrates rapidly upon exposure. Under present conditions it can not be used satisfactorily in locomotives, but answers the need of the community for domestic fuel and for use under stationary boilers. Comparatively little labor is necessary to procure the coal, strip or surface mining being frequently practiced. The coal mine operators have endeavored to improve the quality of their product by briquetting, but so far these attempts have been unsuccessful, failure being due principally to the high cost of binding materials.

No production of coal was reported from North Dakota at the Tenth Census. In 1889 the output was 28,907 short tons. This was almost entirely mined and used by the ranchmen in the immediate vicinity of the openings. In 1902 the production amounted to 226,511 short tons. The state of North Dakota has endeavored to foster its lignite mining industry by compelling its use in all state offices and institutions.

The statistics of production and distribution, by counties, in 1902, are as follows:

TABLE 41.—*Coal production of North Dakota, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Total quantity (short tons).	Total value.	Average price per ton.

Other counties[1]	70,343	3,245	5,820	79,408	93,742	1.18

[1] Includes Burleigh, Emmons, and McLean.

Ohio.—Ohio is one of the 9 states whose coal fields are included in the great Appalachian system. Every county in the eastern half of the state, with the exception of a comparatively narrow belt of 4 counties bordering on Lake Erie, is, or has been, wholly or in part, underlaid by coal. The entire area underlaid by coal in this state has been estimated at 12,000 square miles, distributed over 30 counties in the eastern and southeastern portions. There are no less than 16 workable beds contained in the coal measures of the state, but only 6 of the 16 are of importance. The other 10 are worked by small operators, producing coal for purely local trade. The important beds are known as No. 1, the Block or Sharon coal seam; No. 2, the Wellston; No. 5, the Lower Kittanning; No. 6, the Middle Kittanning; No. 7, the Upper Freeport; and No. 8, the Pittsburg. The coals in these different beds embrace all the varieties of bituminous—steam, gas, coking, and cannel.

The most important producing bed is the Middle Kittanning, or No. 6. In Athens, Hocking, and Perry counties this bed is known as the Hocking Valley seam, which in the 3 counties mentioned produces from 35 to 40 per cent of the total output of the state. It is an excellent steam coal, is popular for domestic use, and also stands high as a furnace fuel, for which purpose it is used in its raw state. The thickness of this seam varies from 12 inches, in Columbiana county, to 13 feet in the Hocking valley.

No. 7, or the Upper Freeport, is second in importance. It is considered as one of the best steam coals in the state, and is consumed chiefly by the railroads. The principal development of this bed is in Guernsey county, which, in 1902, was third in importance as a coal producer.

The Wellston, or No. 2, is also an important producer, the chief operations being in the vicinity of Jackson and Wellston, in Jackson county. It is a free, open burning, noncoking coal, used to a considerable extent in its raw state among the local blast furnaces. It also stands high in popularity as a domestic fuel.

The No. 1, or Block coal seam, produces a good steam and domestic coal, but its chief use is as a blast furnace fuel, for which purpose it is used raw. The furnaces which first substituted coal for charcoal used this coal. What is familiarly known as "Massillon" coal, in the northern part of the state, is mined from this bed.

No. 5, or the Lower Kittanning bed, is best known for its coking qualities, it being the only coal in the state from which a fair grade of coke can be made. Little coke is made from it, however, owing to the proximity and cheapness of higher grade coking coals in Pennsylvania and West Virginia. The coal from this bed finds its principal use as a steam fuel.

No. 8, or the Pittsburg seam, underlies the whole or parts of the counties of Jefferson, Harrison, Belmont, Guernsey, Athens, and Meigs, in the southeastern portion of the state. While not the most important coal bed in the state, it is looked upon as one of the chief future sources of supply, owing to the approaching depletion of some of the other beds.

In the following table is shown the production in 1902, by counties, with the distribution of the product for consumption:

TABLE 42.—*Coal production of Ohio, by counties: 1902.*

[1] Includes Noble, Portage, Scioto, and Washington.

Coal mining in Ohio began during the first quarter of the nineteenth century, but the exact date of the first operations is not known. The first shipment of which there is a record was made from Summit county in 1828, but it is not known how much coal was in this shipment. In 1838 the entire coal production was reported as 119,952 short tons. In 1840 the production was 140,535 short tons; in 1860 it amounted to 1,133,596

tons, and in 1870 it was 2,830,559 tons. The Tenth Census reported an output of 6,008,595 short tons for the fiscal year ending June 30, 1880. The Eleventh Census, for the calendar year 1889, showed a production of 9,976,787 short tons, and in 1902 it reached the maximum record of 23,519,894 short tons. The value of the product in 1889 was $9,355,400, an average of $0.94 per short ton. In 1902 the product was valued at $26,953,789, or $1.15 per ton. It is not believed that the record made in 1902 will be greatly exceeded in the future, as much of the best coal land has been, or is rapidly becoming, exhausted.

As will be seen from the foregoing table, there were 29 counties producing coal in Ohio during 1902. Fifteen of these produced more than 200,000 tons each, thus contributing 22,626,215 tons of the total, or an average of over 1,500,000 tons each. The 14 other counties produced 893,679 short tons, or an average of about 63,800 tons each.

The total amount paid in wages at the Ohio coal mines in 1902 was $16,693,464; other expenses reported amounted to $4,972,023, making a total of $21,665,487. The statistics of the industry are shown in the following table:

TABLE 43.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

[1] Includes Gallia, Holmes, Lawrence, Mahoning, Medina, Morgan, Noble, Portage, Scioto, Summit, Trumbull, Vinton, Washington, and Wayne.

Oregon.—Oregon has only one productive coal field. This is known as the Coos Bay field, in Coos county. It is directly on the coast, giving water transportation for the production, most of which is sent to San Francisco, Cal. According to Prof. J. S. Newberry, coal was mined on Coos bay in 1855, but records of these earlier years are entirely wanting. In 1889 the production amounted to 64,359 tons; in 1902 it was 65,648 tons, showing that the industry has not developed much during the last thirteen years.

Pennsylvania.—The bituminous coal areas of Pennsylvania, which embrace nearly the entire western half of the state, form the northern extremity of the great Appalachian field. Every county in the state west of the Allegheny mountains contains coal beds of economic value, while several outlying basins east of the mountains are also extensively mined. The entire bituminous coal producing area of Pennsylvania is estimated to contain about 15,800 square miles.

In the northern portion of the state the deposits are found principally in detached basins scattered through the counties of Bradford, Cameron, Clinton, Crawford, Elk, Forest, Lycoming, Potter, Tioga, Venango, and Warren. To the south and southwest of these the coal bearing rocks cover all, or nearly all, of the counties of Allegheny, Armstrong, Beaver, Butler, Cambria, Clarion, Clearfield, Fayette, Greene, Indiana, Jefferson, Mercer, Somerset, Washington, and Westmoreland, and portions of Blair and Center counties. The Huntingdon, or Broad Top, basin lies east of the main coal fields, in Bedford and Huntingdon counties.

The counties of Allegheny, Fayette, Greene, Washington, and Westmoreland, in the southwestern corner of the state, contain the upper productive measures, in which is found the famous Pittsburg bed, probably the largest and most productive single coal seam in the world. It is from this bed that the celebrated Youghiogheny gas coal of the Pittsburg district, in Allegheny and Washington counties, is obtained. Farther to the east it produces the famous Connellsville coking coal of Fayette and Westmoreland counties. In Maryland it yields the well known Cumberland coal, while some of the best coals of Ohio and West Virginia are also mined from it. In fact, it may be said that in quality, as in quantity, the coal contained in the Pittsburg bed is equal, if not superior, to any bituminous coal in the world.

Among the other beds in the state are the Upper Freeport, Lower Freeport, Upper Kittanning, Lower Kittanning, Blossburg, Brookville, Sharon, Mercer, Sewickley, and a number of other less important ones, all of which are described in detail in the Twenty-Second

Annual Report of the United States Geological Survey, Part III.

In the production of coal Pennsylvania far exceeds any other state. The combined output of anthracite and bituminous coal in Pennsylvania, from the beginning of the industry until 1902, has each year exceeded 50 per cent of the total production of the United States, the single exception in 1902 having been due to the decrease in anthracite production caused by the long strike. The bituminous product of the state alone has for many years been from 35 to 40 per cent of the total bituminous coal output of the country. In 1902 Pennsylvania produced 98,574,367 short tons of bituminous coal out of a total of 260,216,844 short tons, the percentage for the state being 37.9. In 1889 Pennsylvania produced 36,174,089 tons, or 37.8 per cent of a total of 95,629,026 tons. At the census of 1880 the total bituminous output was 42,831,758 short tons, of which Pennsylvania produced 18,425,163 short tons, or 43 per cent.

The output of bituminous coal in the state of Pennsylvania during the fiscal year ending June 30, 1880, was, as stated above, 18,425,163 short tons and the value of this product was $18,567,129, or an average of $1.01 per ton. The total amount of wages paid during this year was $10,863,583. During the calendar year 1889, Pennsylvania produced a total of 36,174,089 short tons, or nearly double the output of the census year 1880. The value of this product at the mines was $27,953,315, or an average of $0.77 per short ton. The total amount paid in wages in 1889 was $20,738,647. In 1902 the total bituminous production of Pennsylvania was 98,574,367 short tons, or $2\frac{7}{10}$ times that of 1889, and $5\frac{1}{3}$ times that of 1880. The total value of the product in 1902 was $106,032,460, an average of $1.08 per ton, the higher value in 1902, as compared with that of the preceding censuses, being due principally to the demand created for bituminous coal by the shortage in the supply of anthracite. The total amount paid in wages in the bituminous coal mines of Pennsylvania in 1902 was $59,848,902. In 1880 the average wage cost per ton of coal produced was 59 cents; in 1889 it was 57 cents; and in 1902 it was 61 cents. In 1880 the wage cost was equal to 58.4 per cent of the average selling price per ton; in 1889 the wage cost was 74 per cent of the selling price; while in 1902, owing to the high values caused by the strike in the anthracite region, the wage cost was only 56.5 per cent of the selling value.

Of the 24 counties in Pennsylvania from which a production was reported in 1902, there were 2 counties, Fayette and Westmoreland, the output of which exceeded 18,000,000 short tons each. Two other counties, Allegheny and Cambria, each exceeded 10,000,000 tons; 4 others, Washington, Clearfield, Jefferson, and Somerset, each exceeded 5,000,000 tons; and 4 more, Armstrong, Center, Indiana, and Tioga, produced between 1,000,000 and 2,000,000 tons each. The 2 counties of Fayette and Westmoreland, together, produced nearly 5,000,000 tons more than the entire state of Illinois, which was, in 1902, the second state in the production of coal, and 50 per cent more than West Virginia, which ranked third among the coal producing states.

The statistics of production in Pennsylvania, by counties, in 1902, with the distribution of the product for consumption, are shown in the following table:

TABLE 44.—*Coal, bituminous, of Pennsylvania—production by counties: 1902.*

[1] Includes Clinton, Greene, and Lycoming.

The census returns for 1902 show that 236 corporations were engaged in bituminous coal mining operations in Pennsylvania. Of these, 225 reported their capitalization, showing a total capital stock issue of 2,585,468 shares, the par value aggregating $180,338,033. The dividends paid during the year amounted to $8,978,084, while assessments were levied to the amount of $27,600.

The expenses reported for the mining of bituminous coal in Pennsylvania, exclusive of interest on bonds and the costs of the sales departments, were $78,869,528. The statistics for the industry, by counties, the production of which amounted to 200,000 tons or more, are shown in the following table:

TABLE 45.—SUMMARY BY COUNTIES HAVING A PRODUCTION OF 200,000 TONS OR OVER: 1902.

[1] Includes Clinton, Elk, Greene, and Lycoming. (Clinton and Elk counties each had a production exceeding 200,000 tons, but are not shown separately in order to avoid disclosing the operations of individual operators.)

Tennessee.—The great Appalachian coal fields cross the eastern central portion of Tennessee from northeast to southwest, the northern limit extending from Cumberland Gap, in Claiborne county, on the east, to Isham, in Scott county, on the west, a distance of about 45 miles. The coal bearing area narrows considerably toward the south, until near the center of the state, where it again widens out and is divided into two separate parallel basins. Farther south, in Alabama, it broadens still more, and covers nearly 50 per cent of the northern half of that state.

The coal fields of Tennessee are divided into two principal districts, the Jellico, in the northern half, and the Chattanooga, in the southern portion, the geographic division being made by the Emery river, a branch of the Tennessee river, which crosses the field from west to east through the southern portion of Morgan county. The Jellico district is subdivided into three distinct basins, the Jellico and the Middlesboro basins on the north, both of which extend into Kentucky, and the Wartburg basin, in the southern portion of the district. The Chattanooga district is divided into two long parallel basins referred to above, the one to the east being known as the Walden, and the one to the west as the Sewanee.

The Middlesboro basin, the northeastern extremity of the field in Tennessee, embraces portions of Campbell and Claiborne counties in Tennessee, and Bell county in Kentucky. It is a long, narrow syncline, extending in a northeast-southwest direction, and separated from the Jellico basin on the northwest by an unproductive area known as the Pineville anticline. The basin contains several coal beds of workable thickness, but only one, known locally as the Bryson bed, is mined at the present time.

The Jellico basin forms the western part of the coal field in northern Tennessee, and embraces portions of Scott and Campbell counties, in that state, and portions of Whitley and Knox counties, in Kentucky. The coal bearing formations in this basin are thinner than those in the Middlesboro basin, thinning out rapidly toward the northwest. The number and thickness of the coal beds also decrease in this portion. The principal development has been in the eastern part of the basin, along the line of the Southern Railway, where what is known as the Jellico bed is extensively worked. The coal from this bed is well known as a high-grade steam coal.

The Wartburg basin, in the southern portion of the Jellico district, underlies portions of Morgan, Anderson, and Scott counties. The principal developments have been along the eastern border, Oliver Springs, Briceville, and Coal Creek being the chief mining centers.

In the Chattanooga district the Walden basin, on the east, extends through portions of Roane, Rhea, Hamilton, and Marion counties, in a long, narrow belt running from northeast to southwest. The developments have been principally on the eastern border, along the line of the Cincinnati Southern Railway.

The Sewanee basin lies west of the Sequatchie valley, which separates it from the Walden basin. A large portion of the workable coal in this basin is found in what is known as the Sewanee bed, which, next to the Pittsburg bed of Pennsylvania, is probably the most regular and persistent in the United States. The Sewanee bed extends to the northern part of the state and

into Kentucky, where, however, it is at greater depth and is not worked at present.

As in the case of the neighboring states of Kentucky and Alabama, the earliest official record of coal production in Tennessee was that for the census year 1860, when 165,300 tons were reported, although it is known that some coal was mined in all of these states prior to and during the Civil War. The census of 1870 reported the coal production of Tennessee as 149,428 short tons. The Tenth Census, covering the fiscal year ending June 30, 1880, reported the production of the state at 495,131 short tons, valued at $629,724, an average of $1.27 per ton. The Eleventh Census showed the total production of the state to be 1,925,689 short tons, valued at $2,338,309, an average of $1.21 per ton. The increase in production from the Tenth to the Eleventh Census was 289 per cent, and the value of the product increased 271 per cent during the same period. In 1902 the production of Tennessee amounted to 4,382,968 short tons, valued at $5,399,721, an average of $1.23 per ton.

The statistics of production during 1902, by counties, with the distribution of the product for consumption, are shown in Table 46.

TABLE 46.—*Coal production of Tennessee, by counties: 1902.*

Texas.—The coal areas of Texas are included in the Western coal field, which finds its true southern limit in the central part of the state. The Texas areas, however, are separated from the main body of the Western field by the Arbuckle mountains, in the Chickasaw and Choctaw nations of Indian Territory.

Extensive beds of lignite are found underlying the greater part of the prairie region from the northeastern corner of the state to the Rio Grande, and an isolated basin of bituminous coal occurs in the southwestern portion of the state, at Eagle Pass. The principal bituminous mines are located along the line of the Texas and Pacific Railway at Weatherford, in Parker county; at Thurber, in Erath county; and at Bridgeport, in Wise county. Lignite coal is produced in considerable quantities at Rockdale, in Milam county, and at Calvert, in Robertson county. A considerable amount of bituminous coal is also produced at Eagle Pass, in Maverick county, and at Santo Tomas, near Laredo, in Webb county.

No report of coal mining in Texas was made at the Tenth Census. The Eleventh Census reported a total production for 1889 of 128,216 short tons, having a total value of $340,620, or an average of $2.66 per ton. The total amount paid in wages during that year was $256,834. In 1902 the production amounted to 901,912 short tons, valued at $1,477,245, or an average of $1.64 per ton. The wages paid in 1902 amounted to $991,391. Of the total product in 1902, 696,005 short tons, worth $1,326,155, were bituminous coal, and 205,907 short tons, worth $151,090, were of the lignite variety. There were 7 counties in which bituminous coal was produced in 1902 and 9 which produced lignite. The production of lignite in the state during the census year was considerably reduced by reason of the large production and use of crude petroleum for fuel.

The following table shows the production of coal in Texas in 1902, by groups of counties, and the distribution of the product for consumption:

TABLE 48.—*Coal production of Texas, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Total quantity (short tons).	Total value.	Average price per ton.

Utah.—The coal fields of Utah belong to the areas included in the Rocky mountain region. Comparatively little is known in regard to the total areas underlain by coal in this state, as they have received less attention than those in most of the other states of the Rocky mountain system. The principal exploration and developments have been along the lines of transportation, and even here only in somewhat scattered localities. It is therefore impossible to estimate with any degree of accuracy the entire productive area. The known coal fields are estimated to contain about 2,000 square miles. The principal field is located in Carbon, Emery, and Uinta counties, and is an extension westward of the Grand River field of Colorado. So far as known, it exists in a comparatively narrow strip running first southwest and then northwest from the Colorado state line, between the 39th and 40th degrees of latitude. It is traversed near its western limit by the Rio Grande Western Railway, along the line of which the producing mines are located. There is also a somewhat extensive area in the southwestern portion of the state, and one in the southern central portion, neither of which has been developed to any extent on account of its distance from railroad transportation.

The quality of the Utah coal varies from lignite to semibituminous, but none of the lignite beds are operated at the present time. The principal production is of bituminous coal, some of which makes a fairly good coke. Of the total production in 1902, 230,215 short tons were made into coke in Carbon county, which is the principal coal producing county in the state, 95.8 per cent of the total output in 1902 being mined there.

The Tenth Census, covering the fiscal year ending June 30, 1880, reported the coal production of Utah at 14,748 short tons, valued at $33,645. During the calendar year 1889 the output, as reported at the Eleventh Census, was 236,651 short tons, valued at $377,456, or an average of $1.59 per ton. In 1902 the production was 1,574,521 short tons, valued at $1,797,454, or an average of $1.14 per ton.

The statistics of production and distribution, by counties, in 1902 are shown in the following table:

TABLE 49.—*Coal production of Utah, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.

Virginia.—There are three distinct coal producing areas in Virginia. The first of these is the Richmond basin, embracing Henrico, Chesterfield, and Goochland counties, and parts of Powhatan and Amelia, in the eastern portion of the state. This area is placed first, not because of its importance in production at present, but because of the fact that the earliest production of bituminous coal in the United States, as far as known, was obtained from it. The second is an isolated area found in Montgomery and Pulaski counties, in the

southwestern portion of the state, where some semi-anthracite is produced, principally for local consumption. The third, and by far the most important in point of production and area, is the portion of the great Appalachian region which crosses the southwestern corner of the state. A portion of this area, in Tazewell county, contains the famous Pocahontas bed, one of the highest grades of coking and steam coal to be found in the United States. The coal beds in Wise county appear to be a continuation of the Middlesboro coal series of Kentucky. There are found within this coal bearing series in Wise county six different coal seams, all of which are of workable thickness. Developments in Wise county began with the construction of the Clinch valley branch of the Norfolk and Western Railway. It is now by far the most important coal producing county in the state, 76.1 per cent of the entire output being mined in this district.

Although now of little commercial importance, the Richmond basin of Virginia was the first bituminous coal area in the United States to be developed, it having been reported that about fifty-four thousand tons were produced here in 1822. Ten years later, in 1832, the production is reported to have amounted to 132,000 short tons. With the development of other areas more favorably endowed in quality of coal and in ease of mining it, the importance of the Richmond basin as a source of supply rapidly waned, and by the middle of the last century production had almost entirely ceased. Attempts to reestablish the industry in this district in recent years have proved expensive and unsuccessful, and although a small amount continues to be mined for restricted local consumption the field is practically abandoned.

With the development of the Pocahontas region which followed the construction of the Norfolk and Western Railway in 1883, Virginia resumed some importance as a coal producing state. In the census year ending June 30, 1880, the production of the state was reported as 43,079 short tons, valued at $99,802. The first coal shipped from the Pocahontas or Flat Top region (which includes McDowell and Mercer counties in West Virginia as well as Tazewell county in Virginia) was from the Virginia side of the line. This shipment was made by the Southwest Virginia Improvement Company from Pocahontas, and amounted to 68,127 short tons. In the calendar year 1889, according to the Eleventh Census, the production of the state was 865,786 short tons, valued at $804,475, all but about 200,000 tons of this product being from the Pocahontas mines in Tazewell county. The development work in Wise county began in 1891 with the building of the Clinch valley extension of the Norfolk and Western Railway. Shipments began from this new field in 1893. In 1902 the production was 3,182,993 short tons, valued at $2,543,595. The average price per ton in 1889 was 93 cents. In 1902 it was 80 cents.

The statistics of production, by counties, and the distribution of the product for consumption are shown in the following table:

TABLE 51.—*Coal production of Virginia, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at the mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.

[1] Includes Chesterfield, Montgomery, and Pulaski.

Washington.—The coal fields of Washington are found in the western and central portions of the state. There are four principal basins or areas, three of them in the western part of the state, lying in an almost directly north and south line, and one in Kittitas county, near the center. The three former are known as the Northern and Southern Puget Sound coal fields and the Southwestern coal field. The field in Kittitas county, in the central portion of the state, has been designated as the Roslyn basin, from the location of some of its principal operations. The Northern Puget Sound field includes the coal mines located in Skagit and Whatcom counties, in the northwestern corner of the state. The Southern Puget Sound coal field includes the coal areas

in King, Pierce, and Thurston counties, east of the cities of Seattle and Tacoma. The Southwestern field is a small one, lying directly south of Puget sound. The Roslyn field, in Kittitas county, is the most important one in point of production, nearly one-half of the entire output of the state being mined in this county.

Washington is the only one of the Pacific coast states producing true coal, all of the product of California and Oregon being lignite. Some of the Washington coals approach anthracite in character, and some natural coke has been found. A small amount of lignite is also produced in the state. Some of the bituminous coals make a fair grade of coke, and some coke is manufactured in the state each year.

Coal mining began in the middle of the last century, in the vicinity of Bellingham bay, in the northwestern part of the then territory of Washington. Operations in this locality were discontinued in 1879 and have not been resumed. Active development of the other coal fields of the state began about 1882, since which time there has been an almost steady growth in output. At the Tenth Census the coal production from Washington was 145,015 short tons, valued at $389,046. In 1889, according to the Eleventh Census, the output was 1,030,578 short tons, valued at $2,393,238, or an average of $2.32 per ton. Washington's coal production in 1902 was 2,681,214 short tons, valued at $4,572,295, or an average of $1.71 per ton.

The amount paid in wages in 1889 was $1,747,080. The wages paid in 1902 amounted to $3,220,263.

In the following table are shown the details of production, by counties, during 1902, with the distribution of the product for consumption:

TABLE 53.—*Coal production of Washington, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.

West Virginia.—In the amount of area underlaid by coal West Virginia ranks first among the Eastern states, the coal fields of which belong to the Appalachian system. Nearly the entire state (17,280 square miles in all) is included in the coal bearing regions. Within the boundaries of this great coal field in West Virginia there are no less than 21 workable coal seams, chief among which is the Pittsburg bed, which underlies a large portion of southeastern Ohio, southwestern Pennsylvania, and furnishes the famous Big Vein of Maryland's coal areas. This great bed in West Virginia extends from the northern boundaries of the state, where it occurs at the bottom of the upper productive measures, to the Flat Top or Pocahontas districts, in the southern portion, where it is found among the lower coal measures. In the northern part of the state the Pittsburg bed attains a thickness of from 14 to 16 feet, and is exceptionally free from impurities in the form of slate partings or sulphur bands.

No state in the Union is more favored by nature in the number and extent of its bituminous coal seams and in the variety of high-grade qualities of coal than is West Virginia. The best grades of coking, gas, steam, and domestic coals are produced within its borders.

The principal developments in coal production have been along the lines of the three railroad systems crossing the state from east to west. These are the Baltimore and Ohio, which crosses the northern part of the state from Piedmont to Parkersburg, and the Chesapeake and Ohio, and the Norfolk and Western, which traverse the southern coal fields, the former from Hinton and the latter from Pocahontas, on the east, to the Ohio river, on the west. The Coal and Coke Railroad, now building from Elkins to Charleston, and the extensions by the Wabash interests, which have secured control of the West Virginia Central and Pittsburg Railway, are expected to develop some of the rich coal lands in

the interior of the state in the near future. The Deepwater Railroad, building from the station of Deepwater, on the Chesapeake and Ohio, to the Norfolk and Western Railway, will reach hitherto untouched areas lying between those railroads.

West Virginia ranked third in 1902 among the coal producing states, with Pennsylvania first and Illinois second; but with the completion of the railroad extensions now in progress and the additional tonnage which will result therefrom, the chances are that it will in a few years, at most, rank next to Pennsylvania.

Coal production in West Virginia began about 1860 and was entirely from the Piedmont region, to which the Baltimore and Ohio Railroad gave access. Until the completion of the Chesapeake and Ohio and the Norfolk and Western railways all of the output was from the northern part of the state. The Tenth Census, covering the fiscal year ending June 30, 1880, reported the production of coal in West Virginia at 1,829,844 short tons, valued at $2,013,671, or an average of $1.10 per ton. In the calendar year 1889, according to the Eleventh Census, the production was 6,231,880 short tons, valued at $5,086,584, or an average of 82 cents per ton. In 1902 the production amounted to 24,570,826 short tons, valued at $24,748,658, or an average of $1.01 per ton.

A relatively small amount of coal is consumed at iron works in the vicinity of Wheeling, at salt works along the Ohio river, and in some unimportant manufacturing establishments throughout the state. But with these exceptions all of the product, save that for household consumption, is shipped out of the state or is used by the railroads engaged in its transportation. Large quantities are shipped from the eastern parts of the state to the seaports of Baltimore, Norfolk, and Newport News, and from these ports to coastwise and foreign markets, and from the western fields by rail and river to interior and gulf points.

The production by counties in 1902, with the distribution of the product for consumption, is shown in the following table:

TABLE 55.—*Coal production of West Virginia, by counties: 1902.*

[1] Includes Braxton, Brooke, Clay, Gilmer, Grant, Hancock, Lewis, Mason, Monongalia, Nicholas, Putnam, Ritchie, and Upshur.

Wyoming.—The coal fields of Wyoming are included among those of the Rocky mountain area, although most of the productive areas are in the plains region, east of the mountain ranges. There are no less than fourteen different and rather widely separated fields distributed throughout the state. These different areas are known as (1) the Black Hills field, located in Converse and Weston counties, in the northeastern part of the state; (2) the Casper field, a small bituminous area in the eastern part of Natrona county; (3) the Carbon field, and (4) the Hanna field, both in Carbon county; (5) the Rawlins field, in the western part of Carbon and eastern part of Sweetwater county; (6) the Rock Springs field, and (7) the Henrys Fork field, both in Sweetwater county; (8) the Hams Fork, (9) the Almy, and (10) the Sublette fields in Fremont county; (13) the Bighorn, and (14) the Powder river fields in Bighorn county, in the north-central part of the state.

The principal developments have been in the several fields of Carbon, Sweetwater, and Uinta counties, which are traversed by the Union Pacific Railroad, and, to a less extent, in Converse, Natrona, Sheridan, and Weston counties, reached by a branch of the Burlington system. Sweetwater and Uinta counties together produced 72 per cent of the state's total output in 1902.

Coal mining in what is now the state of Wyoming began in 1865 with a product of 800 tons, so far as recorded. In 1868 the production of the then territory amounted to 6,925 short tons, and in 1870 the output was 105,295 short tons. The Tenth Census reported a production of 589,595 short tons, valued at $1,080,451, or an average of $1.83 per ton. According to the Eleventh Census, the production in the calendar year 1889 was 1,388,947 short tons, valued at $1,748,617, or $1.26 per ton. In 1902 the output was 4,429,491 short tons, worth $5,236,339, an average of $1.18 per ton. At the Tenth Census the total wages paid were $579,566; at the Eleventh Census the wages paid amounted to $1,553,947, and in 1902 they were $3,207,545.

The statistics of production, by counties, in 1902, with the distribution of the product for consumption, are shown in the following table:

TABLE 57.—*Coal production of Wyoming, by counties: 1902.*

COUNTY.	Loaded at mines for shipment (short tons).	Sold to local trade and used by employees (short tons).	Used at the mines for steam and heat (short tons).	Made into coke (short tons).	Total quantity (short tons).	Total value.	Average price per ton.
Total	4,144,450	37,101	209,455	38,485	4,429,491	$5,236,339	$1.18
Carbon	352,667	3,374	26,166	.....	382,207	461,338	1.21

Other counties[1]	22	15	64	83,885	2,422	1,760,228	12,747	17	76,513	299,112	2,451,951	3,018,636

[1] Includes Bighorn, Converse, Crook, Fremont, Johnson, Natrona, Sheridan, Sweetwater, and Weston. (Sweetwater and Weston counties each had a production exceeding 200,000 tons, but are not shown separately in order to avoid disclosing the operations of individual operators.)

Occurrence.—The bituminous coal fields are scattered widely over the United States and include altogether an area of something over three hundred and thirty-five thousand square miles. It has been customary to consider as bituminous coal all varieties from lignite to semianthracite. The different varieties merge into each other by such indistinguishable gradations that no absolute line of demarcation is possible. The general term of "bituminous" coal as used in this report includes, therefore, lignite or brown coal, cannel, block, splint, semibituminous, semianthracite, and, as stated, the small anthracite product of Colorado and New Mexico.

The bituminous areas have been divided by the United States Geological Survey into the following subdivisions: (1) Triassic, (2) Appalachian, (3) Northern, (4) Central, (5) Western, (6) Rocky Mountain, and (7) Pacific Coast. They are described briefly, as follows:

1. The Triassic field embraces the coal beds of the Triassic or New Red Sandstone formation, and is worked in the counties of Chesterfield and Henrico in Virginia (generally known as the Richmond basin), and

the coal along the Deep and Dan rivers in Chatham county, N. C. The earliest production of bituminous coal in the United States was made in the Richmond basin of Virginia. The first production from the small area in North Carolina was reported in the census year 1889. Only one commercial mine has been opened in the region and the production has not reached any large proportions during the fourteen years that the mine has been operated.

2. The Appalachian field, which extends from the northern part of Pennsylvania on the north to the central part of Alabama on the south, follows in a southwest direction the Appalachian mountain system. Its entire length is a little over 900 miles and ranges in width from 30 to 180 miles. The area of the coal fields of the Appalachian region is estimated at 70,807 miles, the productive area covering nearly all of western Pennsylvania, the eastern part of Ohio, the western part of Maryland, the southwestern corner of Virginia, nearly all of West Virginia, the eastern part of Kentucky, the east-central part of Tennessee, the northwestern corner of Georgia, and nearly all of northern Alabama.

All of the coals produced in this region are of a bituminous or semibituminous variety, except for a small amount of semianthracite mined in Montgomery county, in the southwestern part of Virginia. Within this region is found bituminous coal of nearly every variety of chemical composition and physical structure. Within its boundaries are found the famous Connellsville coking coal, in Fayette and Westmoreland counties, Pa.; the Clearfield and Pittsburg steam coals; the Youghiogheny river gas coals; the famous smithing coals of Blossburg, Pa., and Cumberland, Md.; the gas and coke producing coals of the upper Potomac and upper Monongahela rivers; the Massillon and Hocking coals of Ohio, noted for their domestic qualities and for their value in the iron reducing furnaces; the coking coals of the Pocahontas Flat Top region; the steam, gas, coking, and domestic coal of the New and Kanawha river series; the Jellico coals of southeastern Kentucky and northeastern Tennessee; and the excellent coking and steam coals of southeastern Tennessee, Alabama, and northwestern Georgia.

The production of bituminous coal in the Appalachian region during 1902 was 173,274,861 short tons. In 1889, at the taking of the Eleventh Census, this region produced 62,972,222 short tons, and in 1880, at the taking of the Tenth Census, it produced 29,834,622 short tons, showing an increase in 1902 of 110,302,639 tons over 1889 and of 143,440,239 tons over 1880.

3. The Northern coal field lies altogether in the lower peninsula of Michigan, between Lake Michigan and Lake Huron, extending from Jackson county on the south to Roscommon county on the north, and from Tuscola county on the east to Kent county on the west. It embraces an area of approximately 7,500 square miles. It is the only known coal field lying in the drainage basin of the St. Lawrence river within the limits of the United States. The northeastern edge of the field is penetrated by Saginaw bay, through which, with the Saginaw river, it is given easy access to Lake Huron and thence to the ports of the Great Lakes.

Although coal was produced in this region as early as 1835, it is only within the last few years that the production has amounted to any great importance. In 1880 the Northern coal field produced 100,800 short tons; in 1889 the output had fallen to 67,431 tons. The active development of the region really began in 1897 and by 1901 the production had amounted to 1,241,241 short tons. Labor troubles in the census year of 1902 reduced the output to 964,718 short tons.

4. The Central coal field includes all the coal producing areas of Indiana, Illinois, and western Kentucky. It extends from the northern part of Illinois (most of the central and southern parts of the state being underlain by workable coal seams) to the central part of western Kentucky. The field is estimated to contain an area of 42,900 square miles in Illinois, 9,300 square miles in Indiana, and 5,800 square miles in Kentucky, making a total for the entire field of 58,000 square miles. The coal field underlies 80 counties in Illinois, 26 in Indiana, and 20 in Kentucky, although coal is not at present mined in all of the counties in any of the three states.

It is from the Indiana portion of this field that most of the well-known "block" domestic coal is produced. In the Kentucky portion of the field the coal grades into a quality suitable for coking purposes, and considerable quantities of coke are produced in this portion of the field, although practically no coke is made in either Illinois or Indiana.

The Central coal field, while fourth in size among the coal fields of the United States, is second in producing importance. Illinois, which contains nearly three-fourths of the entire area, was second in 1902 among the coal producing states. The production from this entire field in 1902 was 46,133,024 short tons, an increase of a little over 180 per cent as compared with 1889, when the production was 16,240,314 tons, and of 466 per cent as compared with 1880, when the production was 8,150,195 tons.

5. The Western coal field forms a practically continuous belt of coal measure rocks from northern Iowa in a southwesterly direction through central Texas to the Rio Grande, a distance of 880 miles, and underlying a total of 94,076 square miles. It includes the coal bearing areas of Iowa, Missouri, Nebraska, Kansas, Indian Territory, Arkansas, and Texas.

Within its boundaries are found all the varieties in-

cluded under the general head of bituminous coal, from lignite to semianthracite, immense areas in Texas being underlain by lignite, while semianthracite is found in Indian Territory and Arkansas. Coking coals are produced in Indian Territory, cannel coal is produced in Missouri, and block coal is mined in Iowa. Most of the coal produced is of the dry, noncoking variety of bituminous coal.

The production in the census year of 1902 amounted to 20,727,495 short tons, as compared with 10,036,356 short tons in 1889 and 3,212,787 short tons in 1880. The development in this region during the last twenty years has been of extraordinary rapidity.

6. The Rocky Mountain coal field includes the productive areas in the states lying along the Rocky mountain range and also those of North Dakota, although the coal fields of the latter state do not lie within the Rocky mountain system. The states from which coal has been produced in this field are Colorado, Idaho, Montana, Nevada, North Dakota, Utah, and Wyoming, and the territory of New Mexico. Idaho and Nevada have produced insignificant amounts for purely local consumption. South Dakota has produced an insignificant amount of lignite, but none in the last few years. The known areas cover a little over one hundred thousand square miles of territory.

The production from the entire region in 1902 was 16,149,545 short tons, as compared with 5,048,413 short tons in 1889 and 1,067,314 short tons in 1880.

7. The Pacific Coast field embraces the coal producing areas in the 3 states bordering on the Pacific ocean—California, Oregon, and Washington. The coals are all of the Tertiary age and are largely lignitic in character. The only bituminous coal produced in the Pacific coast region is mined in Washington, all of the product from California and Oregon being lignite. Some of the bituminous coals in Washington possess good coking qualities, and some coke is made in the state each year.

The first production in this region was, so far as known, in California in 1861. The first coal mined in Washington was, so far as known, produced in 1880, and it was not until 1885 that any coal was reported to have been produced in Oregon. All of the growth in the last two decades has been in the Washington coal fields. The production in California has decreased since 1880. The production of Oregon in 1902 was about the same as in 1889, and 30 per cent more than in 1885. The production of Washington, however, has increased from 145,015 short tons in 1880 to 1,030,578 tons in 1889 and 2,681,214 tons in 1902. The production from the entire field has increased from 425,170 short tons in 1880 to 1,214,757 tons in 1889 and to 2,834,058 tons in 1902. A small production from Alaska, 2,212 tons, is included in this production for 1902.

Table 59 is a detailed summary of the anthracite coal industry by counties, and Table 60 is a detailed summary of the bituminous coal industry by states and territories.

PETROLEUM

PETROLEUM.

By F. H. Oliphant.

The only census statistics for the production of crude petroleum comparable with those of 1902 are the statistics for 1870 and 1889. No census of the industry was taken in 1860, the year following the drilling of Drake's well, and the census of 1880 was chiefly for refined petroleum, although some data were given for the crude. In Table 1, which is a comparative summary from 1860 to 1902, the production shown for 1860 is the estimate published by the United States Geological Survey, and the figures for 1880 are selections from tabulations in the census report. However defective the basis of comparison, the table is sufficient to indicate the progress made from one period to another in the rise of this important industry.

Table 1.—*Comparative summary: 1860 to 1902.*

	1902	1889	1880	1870	1860
Number of wells	118,671	35,163	15,009	[1] 2,314	([2])
Number of operators	29,522	([2])	([2])	([2])	([2])
Salaried officials, clerks, etc.:					
Number	3,033	[3] 173	([4])	([4])	([2])
Salaries	$2,986,768	$163,156	([4])	([4])	([2])
Wage-earners:					
Average number	[5] 17,552	[3] 22,366	11,477	4,488	([2])
Wages	$13,242,361	$8,383,744	$7,179,000	$3,995,030	([2])
Contract work	$12,956,631	([2])	$3,730,000	([2])	([2])
Miscellaneous expenses	$15,811,726	([2])	([2])	([2])	([2])
Cost of supplies and materials	$17,781,512	$9,505,935	$3,174,160	$1,401,945	([2])
Product:					
Quantity, barrels of 42 gallons	[6] 89,275,302	35,163,513	26,286,123	4,315,798	500,000
Value	[6] $71,397,739	$26,963,340	$24,600,638	$19,304,224	$4,800,000

[1] Establishments.
[2] Not reported.
[3] Foremen included in wage-earners.
[4] Not reported separately.
[5] The apparent decrease in the wage-earners for 1902, as compared with 1889, is caused almost entirely by the difference in the methods of computing the average number at the two censuses.
[6] The United States Geological Survey reports 88,766,916 barrels, valued at $71,178,910, which represents the product marketed. The Census figures represent the petroleum produced.

The statistics showing the production of petroleum in the United States during the decade between the census years 1889 and 1902 indicate a very remarkable increase in the quantity and value of this important natural product. The number of barrels produced in 1889 was 35,163,513, valued at $26,963,340. The number of barrels produced in 1902 was 89,275,302, valued at $71,397,739, which shows an increase of 153.9 per cent in quantity and 164.8 per cent in value. The average increase in quantity for each of the twelve years between the dates named was 12.8 per cent and in value 13.7 per cent. The conditions that brought about this increase were varied and extensive, the most conspicuous of which was the opening up of several large pools in northwestern Pennsylvania during 1890 and 1891, followed by the development of the McDonald pool near Pittsburg, which reached its zenith in 1891, giving to Pennsylvania in that year the greatest production in its record.

In Ohio, from its two fields, there has been a gradual increase, the production reaching its height in 1896, with a slight decline to the close of 1902. In West Virginia, from 1890 to 1900, there was a remarkable increase in the production, the greatest output being in the latter year; this has since been followed by a gradual decline.

In Indiana there have been almost continual gains since the beginning of 1890 to the close of 1902. In California, during the period beginning with 1894 and ending with 1902, there has been a remarkable increase in production, this being most marked from the beginning of 1900 up to the close of 1902. Since the year 1898 the production in Texas has been increasing at a wonderful rate; the gain in 1902 compared with 1901 was the greatest on record. A decided increase was also shown in Kansas.

While the combined output of the older fields in the northeastern portion of the United States showed only a very slight decline, the fields of the Southwest and West developed an extraordinary increase in new production, although this production was of a quality inferior to that of the older fields and was marketed at a less value.

The total number of all wells at the close of 1902, which includes the dry holes and those abandoned, was 118,671; of this number 108,604 were productive wells.

Wells and tankage.—The total number of wells drilled in 1902, both dry holes and productive, the number of flowing and pumping wells, the number of wells

operated, the number of wells that produced petroleum and the number abandoned, and the number of tanks at the wells and their capacity for receiving the output are shown in the following table:

TABLE 2.—RECORD OF WELLS AND TANKAGE, BY STATES AND TERRITORIES: 1902.

WELLS AND TANKAGE.	United States.	California.	Colorado.	Indiana.	Kansas.	Kentucky.	New York.	Ohio.	Pennsylvania.	Texas.	West Virginia.	All other states and territories.

[1] Includes wells distributed as follows: Illinois, 2; Indian Territory, 13; Louisiana, 7; Michigan, 12; Missouri, 5; Oklahoma, 3; Tennessee, 4; Wyoming, 11.

In the entire United States there were 15,506 wells drilled in 1902; of this number 3,158 were dry holes—that is, wells which did not produce petroleum in sufficient quantity to justify pumping them or were totally destitute of petroleum. The number of producing wells drilled in 1902 was, therefore, 12,348. There were 694 flowing wells producing petroleum and 107,950 wells that were pumped, making a total of 108,644 producing wells in the United States in 1902. The greatest number of flowing wells was in West Virginia, where they numbered 500.

Flowing wells do not usually continue to flow for long periods, and are found only in comparatively new territory, where the pressure of natural gas still remains in the rock. Wells that are pumped are usually operated by sucker rods—wooden rods with iron sockets reaching down inside a 2-inch pipe or tubing to a working barrel at the bottom containing valves, the packing being made by leather cups. The motion is from 10 to 18 inches, 20 to 60 strokes per minute. The depth of wells which produce petroleum varies from 250 to 3,300 feet; the latter depth is attained only in West Virginia. Of the total producing wells 70.8 per cent are located in the states of Ohio and Pennsylvania, the former state leading the latter by 1,250 wells. The number of producing wells in New York was 8,178 and in Indiana 8,224. California comes next with 2,574 producing wells, 35 of which are flowing. The number of wells in the United States abandoned during the year was 6,869, which is more than half of the productive wells drilled in 1902. The greatest number of abandoned wells in 1902 was in Ohio, where the number reached 2,533. The number of abandoned wells in Pennsylvania was 1,879; in West Virginia, 1,322; and in Indiana, 772.

The tanks vary in capacity from 5 to 1,200 barrels, and are connected with the pipe line system by pipes. Each tank is usually measured and numbered by the pipe line company and the number of barrels to the inch noted. A valve that is attached to the bottom of the tank and the lead line is locked by the pipe line company and is only opened when the number of inches of petroleum in the tank is measured by the gauger, and it is closed by him at the end of the run.

Capital stock of incorporated companies.—The capital stock and bonded indebtedness of incorporated companies are reported by states and territories in the following table:

TABLE 3.—CAPITALIZATION OF INCORPORATED COMPANIES: 1902.

[1] Includes Illinois, Indian Territory, Louisiana, Michigan, Missouri, Oklahoma, Tennessee, and Wyoming.

The total amount of capital stock issued and funded debt outstanding was $330,905,859. The number of shares of common and preferred stock authorized amounted to 330,456,514. Of this amount 213,116,629 shares were issued, the par value being $324,186,603, upon which $10,771,936, or 3.3 per cent, was paid as dividends. The par value of the common stock issued was $321,036,942 and the dividends paid upon it amounted to $10,744,563; on the issue of preferred stock, the par value of which was $3,149,661, the dividends paid amounted to $27,373. The par value of the bonds issued amounted to $6,719,256 and the interest paid was $297,333, or 4.4 per cent.

The greatest amount of stock was issued in the state of California, the par value being $108,043,132, upon which $1,190,012 in dividends was paid. Texas was next, with a par value of $75,368,714, upon which $655,216 was paid in dividends. Ohio was third; the par value of stock issued amounted to $37,358,100, and the dividends paid, to $4,715,322. In Pennsylvania the par value of stocks was $27,075,100, on which dividends amounting to $945,372 were paid. In West Virginia the par value of the stock issued amounted to $29,706,200 and the dividends to $980,846.

Speculative companies, numbering 1,200 or more, have been organized since 1900, representing a capitalization estimated to be at least $600,000,000. A large amount of stock has been issued by such companies operating in Texas, California, Colorado, Louisiana, and Kentucky.

Employees and wages.—The total number of persons regularly employed in the production of crude petroleum in 1902 was 20,585, who received $16,229,129 in salaries and wages. Of this number 3,033 persons were employed as salaried officials, clerks, etc., and received $2,986,768. The total average number of wage-earners was 17,552, who received $13,242,361. The average number of wage-earners employed each month during 1902 is shown by states and territories in the following table:

TABLE 4.—AVERAGE NUMBER OF WAGE-EARNERS EMPLOYED DURING EACH MONTH: 1902.

	United States.	California.	Colorado.	Indiana.	Kansas.	Kentucky.	New York.	Ohio.	Pennsylvania.	Texas.	West Virginia.	All other states and territories.[1]

[1] Includes Illinois, Indian Territory, Louisiana, Michigan, Missouri, Oklahoma, Tennessee, and Wyoming.

The greatest number of employees is found in Pennsylvania. Although Ohio, West Virginia, Texas, and California produced more petroleum, they employed fewer wage-earners, because more of their wells were large producers. Pennsylvania employed 32 per cent of the wage-earners and produced only 13.5 per cent of the entire product, the wells with one exception being pumping wells. On the other hand, Texas employed only 4.1 per cent of the wage-earners, although producing 20.7 per cent of the petroleum; and California with 6.3 per cent of the wage-earners yielded 15.7 per cent of the petroleum. There was very little fluctuation in the number employed, taken as a whole.

The average number of wage-earners by occupations at specified daily rates of pay is shown in the following table:

TABLE 5.—*Average number of wage-earners at specified daily rates of pay, by occupations: 1902.*

RATE PER DAY (DOLLARS).	All occupations.	Engineers.	Firemen.	Machinists, blacksmiths, carpenters, and other mechanics.	All other wage-earners.

4.00 to 4.24	25	7	.....	16	2
4.25 and over	289	16	3	265	5

Nearly 57.2 per cent of the wage-earners connected with the production of petroleum in 1902 received between $2.25 and $2.49 per day. Only about eight-tenths of 1 per cent received less than $1.50 per day. Of the 12,951 engineers, 76.2 per cent received between $2.25 and $2.49 per day, and only 1.4 per cent received less than $1.75 per day. Of those rated as mechanics, including blacksmiths, carpenters, and others of like occupation, 63.7 per cent received from $1.50 to $2.74 per day and 19.1 per cent from $2.75 to $3.24. About four-tenths of 1 per cent of this class of wage-earners received less than $1.50 per day. Nearly 84 per cent of "all other wage-earners" received from $1.50 to $2.74 per day.

Contract work.—The amount paid for contract work was $12,956,631, or 44.4 per cent of the total amount paid for salaries, wages, and contract work. Nearly all the building of rigs, drilling of new wells, torpedoing and cleaning out was done by contract work, the cost of which also includes the value of material furnished and a profit to the contractor. There are numerous instances where the owners of wells contracted with individuals for the work necessary to pump and care for a cluster of wells, dividing the pipe line runs pro rata. The entire number thus employed is estimated to be 12,800.

A concise statement covering the entire petroleum producing fields is difficult to secure. The drilling of a well requires from ten days to seven weeks, and, when the work is completed, the crew is removed by the contractor usually to some distant location. A crew is temporarily employed to clean out a well after it has been torpedoed. In torpedoing wells, building tanks, connecting pipe lines, and in other matters of labor and materials furnished which are paid for in the lump, a similar condition of affairs existed, the workmen going from well to well or from district to district. Thus it is that no detailed account can be secured showing what part of the disbursements for this kind of work went to labor under the head of "cost of contract work" and what to "cost of supplies and materials."

Supplies, materials, and miscellaneous expenses.—Under supplies and materials are included casing, tubing, pipe, engines, boilers, tanks, etc., and renewals. Under miscellaneous expenses are included rent of offices, taxes, insurance, etc., and royalties and rent of wells and plants. The entire expense reported under the above headings for the year 1902 was $33,593,238.

Mechanical power.—For the producing wells a total of 910,077 horsepower was reported, of which 907,854 horsepower was owned by the operators and 2,223 horsepower was rented. Of the power owned 666,177 horsepower was furnished by 41,797 steam engines, 240,505 by 12,606 gas or gasoline engines, and 1,172 horsepower by 37 other prime motors. In addition, 2 electric motors with a capacity of 25 horsepower were reported. The steam engines averaged approximately 16 horsepower, and the gas or gasoline engines 19 horsepower. The rented power consisted of 125 electric and 2,098 horsepower of other kinds. The electric power, both owned and rented, was reported from California. Over 54 per cent of the horsepower was employed in Pennsylvania.

Production.—The production of crude petroleum in the United States in 1902 was 89,275,302 barrels—greater than ever before and nearly equal to that of Russia and all the other petroleum producing countries of the world combined. This was the product of 108,644 wells, an average of 822 barrels per well, or 2.14 barrels per well per day. The quantity and value of the crude petroleum produced in the United States in 1902 are given by states and territories, arranged in the order of their production, with percentages of the whole, in the following table

TABLE 6.—*Quantity and value, with percentages, by states and territories: 1902.*

STATE OR TERRITORY.	Barrels.	Per cent.	Value.	Per cent.
Total	89,275,302	100.0	$71,397,739	100.0

Oklahoma	100	(1)	750	(1)

[1] Less than one-tenth of 1 per cent.

Of the total production from 1859 to 1902, Pennsylvania and New York produced 53.9 per cent, Pennsylvania probably producing nearly 50 per cent, and New York about 4 per cent. Ohio produced 24.4 per cent; West Virginia, 11.3 per cent; Indiana, 3.9 per cent; Texas, 2.1 per cent; California, 3.6 per cent; leaving eight-tenths of 1 per cent for the remaining states and territories, which include Colorado, Illinois, Indian Territory, Kansas, Kentucky, Louisiana, Michigan, Missouri, Oklahoma, Tennessee, and Wyoming. It is estimated that from the crude petroleum produced in the United States in 1902, there were obtained 1,938,669,445 gallons of refined petroleum products, which represents about 72 per cent of the total refined products for the world.

In the year 1902 the United States for the first time in five years surpassed the petroleum production of Russia. In that year these two countries together produced 91.4 per cent of the total output, as compared with 93.2 per cent in 1901 and 94.1 per cent in 1900. Indications seem to point to the fact that the wide distribution of petroleum in nearly all countries of the globe, and the more successful methods of securing its profitable production and transportation, will cause an increase in the yearly output of the entire world for a number of years.

The very high grade of a large part of the crude petroleum produced in the United States gives this country a very large percentage of the production of the higher grades of refined petroleum. A careful estimate places the refined product secured from the crude in the United States at 52 per cent of its entire production, compared with 21 per cent of the entire output of Russia and 28 per cent for the average refined products secured from the crude produced in all other countries. It is estimated that the proportion of refined products—the illuminating, naphtha, and lubricating petroleums—produced in the United States in 1902 amounted to 72.1 per cent of the entire production of the world for that year; while Russia produced 25.2 per cent and all the other countries 2.7 per cent. The United States, therefore, produced nearly 2.6 barrels of refined production for every barrel produced by the rest of the world.

The most valuable grades of crude petroleum, from which the very best grades of refined products are secured, continue to be produced in the United States, principally in the northeastern portion, from the Appalachian and Lima-Indiana fields. The lubricating products made from the crude petroleum produced in this section are also superior to any others produced in the entire world. It supplies almost the entire demand for lubricants in the United States, and large quantities of it are marketed abroad. About 45 per cent of the entire quantity of refined petroleum products manufactured in the United States is marketed abroad.

In the following table is given a statement of the total quantity and value of all crude petroleum produced and marketed in the United Stated in 1902 and 1901, by states and territories and important districts, and average price per barrel:

TABLE 7.—*Production, value, and average price per barrel, by states and territories, and by districts: 1902 and 1901.*

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

STATE, TERRITORY, OR DISTRICT.	1902			1901

Wyoming	6,253	43,771	7.00	5,400	37,800	7.00

[1] In addition to this quantity, 76,538 barrels were produced in Kentucky, valued at $41,353; 489 barrels in Missouri, valued at $842; and 431,359 barrels in Texas, valued at $176,634, which were tanked and unsold by the producing companies. These appear in the totals shown in the census tables, making the aggregate 89,275,302 barrels, valued at $71,397,739.

[2] Production of light oil in Petroleum and Volcano included with West Virginia's production.

Petroleum and natural gas.—Petroleum and natural gas are intimately connected in composition and occurrence, one being a gaseous and the other a liquid hydrocarbon, and with but few exceptions they are associated in all of the fields, the gas occupying the

upper portion of the same strata which contains the petroleum. In many localities, during cold weather, a small portion of the more volatile naphthas are often condensed from the natural gas and deposited in the pipe lines. Of the combined value of the two, petroleum amounted to a little less than 70 per cent, and natural gas to a little more than 30 per cent.

In combined value they rank next to pig iron and coal in the list of the crude minerals produced in the United States in 1902. The following table presents the combined value of petroleum and natural gas by states and territories in order of values:

TABLE 8.—*Value of petroleum and natural gas: 1902.*

STATE OR TERRITORY.	Total value.	Value of petroleum.	Value of natural gas.
Total	$102,265,602	$71,397,739	$30,867,863
Pennsylvania	29,618,276	15,266,093	14,352,183
Ohio	23,112,817	20,757,359	2,355,458
West Virginia	22,430,498	17,040,317	5,390,181
Indiana	13,607,966	6,526,622	7,081,344
California	4,994,265	4,873,617	120,648
Texas	4,189,684	4,174,731	14,953
New York	1,877,323	1,530,852	346,471
Kansas	1,116,895	292,464	824,431
Colorado	486,583	484,683	1,900
Kentucky	538,448	172,837	365,611
All other states and territories[1]	292,847	278,164	14,683

[1]Includes Illinois, Indian Territory, Louisiana, Michigan, Missouri, Oklahoma, Tennessee, and Wyoming.

Exports.—Petroleum probably reaches a wider market than any other article in the whole list of our exports. It has penetrated every quarter of the globe and is without a rival in its illuminating and lubricating qualities.

Formerly petroleum was exported in barrels or cans; to-day it is largely transported in bulk, by tank steamers, from which it is delivered to receiving tanks at the various ports. Only from ten to twelve hours are required to receive or discharge a large cargo. From these receiving points it is distributed to tank cars, which reach the inland cities and towns, where it is again delivered to tanks, and finally reaches the consumer by tank wagons. A portion of it for many of the seaport towns in warm climates is still transported in cans.

The tank steamers engaged in the transportation of petroleum are modern ships throughout, and have a number of square iron tanks arranged on each side of the center line. There are a number of bulkheads made double, with water spaces between them, which separate the engine and the boilers and the quarters for the crew from the oil tanks. Some of these tank ships have a capacity of 60,000 barrels, or from 2,500,000 to 2,800,000 gallons.

In 1902 there were exported from the United States 1,064,233,601 gallons of petroleum and its products; this amount was only exceeded in the year 1901, when there were 1,079,074,519 gallons exported.

In 1902, of the total quantity exported from the United States, 50.2 per cent was loaded at New York, which is thus shown to be the leading export city, 32.4 per cent at Philadelphia, 9.2 per cent at points on the Delaware river, and 3.9 per cent at Baltimore. Lately Port Arthur and Sabine City, Tex., have become ports of export, and, together with Boston and Charlestown, Mass., and other districts, whose exports make up the remaining 4.3 per cent of the total.

The first large shipment of petroleum was in 1861, when the brig *Elizabeth Watts*, 224 tons register, sailed from Philadelphia with a full cargo of petroleum in barrels. Doctor Crawford, consul at Antwerp, had received barrels of refined petroleum previous to this shipment. For the year 1862 there were exported from Philadelphia 2,664,280 gallons, followed by 4,680,174 gallons in 1863.

In the following table the production of petroleum in barrels and their equivalent in gallons are given, together with the quantity and value of the total exports; also the quantity in gallons of the crude and manufactured products exported from 1864 to 1902, inclusive.

TABLE 9.—PRODUCTION AND EXPORTS OF CRUDE AND MANUFACTURED PRODUCTS: 1864 TO 1902.

[1] Exports are for fiscal years from 1893 to 1896, inclusive.
[2] In addition, 4,325 barrels of crude oil were produced in Kentucky and Tennessee in 1896, 4,377 barrels in 1897, 19,125 barrels in 1898, and 13,578 barrels in 1899, for which, as none was sold or used, no value could be given.
[3] Includes 41,405 barrels of oil sold in Kentucky and Tennessee in 1900, but produced in previous years.
[4] In addition to this quantity, 508,386 barrels were produced, but not marketed.

Of the total production of crude petroleum in the United States over 38 per cent is exported as crude or refined products, leaving nearly 62 per cent, which is consumed at home. The home consumption has been growing of late, as well as the production of crude petroleum of second quality. As before noted, the total exports, for the first time, exceeded one billion gallons in 1901. There was a slight decline in 1902, yet the amount for the year was still over one billion gallons. The exports of lubricating and paraffin products have for a number of years shown a steady increase.

Foreign markets.—The following table shows the foreign markets for American petroleum and petroleum products for the nine fiscal years ending June 30, 1902:

TABLE 10.—EXPORTS OF PETROLEUM IN ITS VARIOUS FORMS FROM THE UNITED STATES, BY COUNTRIES, FOR THE FISCAL YEARS 1894 TO 1902.

[United States Geological Survey, "The Production of Petroleum," 1902.]

Percentage of each	73.7	3.8	4.2	17.2	1.1

[1] In barrels: Europe, 710,070; North America, 10,916; all other countries, 669.
[2] Includes all other countries.

Of the total exportation of all varieties of petroleum during the fiscal year ending June 30, 1902, there was shipped to Europe 73.7 per cent, to Asia and Oceania 17.2 per cent, South America 4.2 per cent, North America 3.8 per cent, and to Africa 1.1 per cent.

Of that portion which went to Europe, exclusive of "residuum," the exports of which are given as 710,070 barrels (or 29,822,940 gallons), the United Kingdom received 32.5 per cent, Germany 20 per cent, the Netherlands 16.1 per cent, France 13.6 per cent, and Norway and Sweden 4 per cent, the remaining 13.8 per cent being divided among Belgium, Denmark, Italy, Portugal, Spain, and the other European countries.

Of the total amount of illuminating oil exported, Japan consumed 7.1 per cent and China and Hongkong 8.9 per cent. These countries consumed over 71 per cent of the total amount exported to Asia and Oceania.

Prices.—The price per gallon of refined petroleum at New York and Philadelphia in 1902, when loaded into bulk steamers, ranged from 4.65 cents to 5.65 cents for oil in bulk; from 7.15 cents to 8.15 cents for oil in barrels; and from 8.40 cents to 10.60 cents for oil in cases; the minimum prices prevailed at the beginning and for the greater part of the year, and the maximum at the close. There was a slight advance in prices in May, June, and July, followed by a decline, and a second advance toward the close of the year.

The average yearly prices in cents per gallon of 70° Abel test refined oil in barrels at New York for the years 1892 to 1902, inclusive, were as follows:

Average yearly prices per gallon of refined petroleum: 1892 to 1902.

YEAR.	Average price (cents per gallon).	YEAR.	Average price (cents per gallon).
1892	6.07	1898	6.32
1893	5.24	1899	7.98
1894	5.19	1900	8.45
1895	7.36	1901	7.48
1896	6.98	1902	7.33
1897	5.91		

The monthly average prices per gallon of crude and refined illuminating petroleum exported in bulk, for the years 1899 to 1902, inclusive, are shown in the following table:

TABLE 12.—*Monthly average prices per gallon of oil exported from the United States in bulk: 1899 to 1902.*

PRODUCTION IN THE UNITED STATES SINCE 1859.

The production of crude petroleum in the United States by states, since the commencement of production in 1859, is shown in the following table:

TABLE 13.—PRODUCTION, BY STATES AND TERRITORIES: 1859 TO 1902.

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

[Barrels of 42 gallons.]

[1] In addition to this quantity it is estimated that for want of a market some 10,000,000 barrels ran to waste in and prior to 1862 in the Pennsylvania fields; also a large quantity in West Virginia and Tennessee.
[2] Includes all production prior to 1876 in Ohio, West Virginia, and California.
[3] Includes all production prior to 1876.
[4] Includes all petroleum produced in Kentucky and Tennessee prior to 1883.
[5] In addition to this quantity, 4,325 barrels of crude oil were produced in Kentucky and Tennessee in 1896, 4,377 barrels in 1897, 19,125 barrels in 1898, and 13,578 barrels in 1899, for which, as none was sold or used, no value could be given.
[6] Includes the production of Michigan.
[7] Includes production of Michigan and small production in Oklahoma.
[8] Does not include 508,386 barrels produced, but not marketed.

Since the year 1888, when the entire production was only 27,612,025 barrels of crude petroleum, there has been on the whole a gradual increase. The year 1891, when the production reached 54,292,655 barrels, had the largest output up to that date, owing chiefly to the increase in Pennsylvania petroleum, caused by the opening up of some wonderfully prolific territory at McDonald, in Allegheny and Washington counties. From 1891 to 1893 there was a considerable decline in the production, the latter year having the smallest output since 1891. After 1894 there was an increase, and the year 1896 showed a larger production than any year up to that date. The figures were not surpassed until 1900, when the production was 63,620,529 barrels. The year 1901 showed substantial gains over 1900, while that of 1902 was nearly 20,000,000 barrels greater than 1901. This increase was due chiefly to the increased production of Texas, California, and Louisiana. The grade of the oil, however, was generally inferior to that of older fields. The production of the high grades of petroleum produced in the Appalachian, Lima-Indiana, Kansas, Corsicana, and the Colorado fields remained about the same as in the previous year. From the output of these fields a superior grade of refined products is manufactured. The poorer grades of petroleum produced in Texas, Louisiana, and California were marketed in 1902, principally for fuel, at much reduced values, although the average price received for the better grades increased about 4 cents per barrel over the average price in 1901.

It will be seen in Table 13 that the production of crude petroleum in the United States from the beginning of the

petroleum industry in 1859 to the end of 1902 was 1,165,290,248 barrels. Allowing 5.6 cubic feet for the cubical contents of a barrel of 42 gallons, this quantity would occupy 6,525,625,389 cubic feet and would require a cube 1,869 feet on each side to contain it. It would fill a tank the base of which was 1 mile square to a height of 234 feet. This quantity would fill 38,843 ordinary tanks containing 30,000 barrels; allowing 90 feet for their diameter, if they were placed side by side they would reach a distance of over 662 miles. Again if $2\frac{1}{2}$ feet be taken as the height of a barrel of 42 gallons and if there were sufficient barrels to contain this amount of crude petroleum and the barrels were laid so that their heads would touch, they would encircle the globe 2.27 times. Allowing $3\frac{1}{2}$ barrels to equal the fuel value of a ton of the average coal, the amount represents a fuel value of 332,940,071 tons of coal. There were 301,590,439 tons of coal produced in the United States in the year 1902; the fuel value of the petroleum produced in 1902 would equal that of 25,507,229 tons of coal. The value of the petroleum produced since 1859 to the close of 1902 was $1,166,885,363; the average price was therefore $1.0014 per barrel. The amount invested in wells and fixtures at the end of 1902 is estimated at $290,000,000.

The quantity and value of the crude petroleum produced in the United States for each year since 1859 is shown in Table 14.

TABLE 14.—*Quantity and value of production: 1859 to 1902.*

[1] Does not include 508,386 barrels produced, but not marketed.
[2] Includes 41,405 barrels of oil sold in Kentucky and Tennessee in 1900, but produced in previous years.
[3] In addition to this total 4,325 barrels of crude oil were produced in Kentucky and Tennessee in 1896, 4,377 barrels in 1897, 19,125 barrels in 1898, and 13,578 barrels in 1899, for which, as none was sold or used, no value could be given.

Percentages of production in the Appalachian, Lima-Indiana, and all of the other fields combined for the years 1896 to 1902, inclusive, are as follows:

Per cent of total crude petroleum produced in the several fields: 1896 to 1902.

FIELD.	1902	1901	1900	1899	1898	1897	1896
Total	100.0	100.0	100.0	100.0	100.0	100.0	100.0
Appalachian	36.1	48.5	57.0	58.0	57.3	58.3	55.7
Lima-Indiana	26.3	31.6	34.2	35.4	36.7	37.7	41.4
All other	37.6	19.9	8.8	6.6	6.0	4.0	2.9

During the last three years there has been a constant decline in the proportionate production of crude petroleum in the Appalachian and Lima-Indiana fields, and a very rapid increase in the production of the fields yielding lower grade or fuel oils. In 1896 only 2.9 per cent was produced outside of these two older fields. In 1902 the outside production was 37.6 per cent, of which California produced about 15.7 per cent and Texas 20.4 per cent, leaving only about 1.5 per cent for the remainder of the sections outside the Appalachian and Lima-Indiana fields.

Appalachian field.—This great field follows the northwestern flank of the Appalachian mountains in a generally southwestern direction from New York to Alabama, a distance of about 650 miles. It embraces all the producing regions in New York, Pennsylvania, West Virginia, Kentucky, and Tennessee, and a southeastern portion of Ohio. It includes within its area not less than 40,000 square miles. It is the oldest producing field in the United States.

The first well drilled near Titusville, Pa., in 1859, was followed by a great development which has been succeeded by a vast number of successful operations, extending up to the present time. The great portion of the petroleum output of this field is of a superior quality, and produces a larger proportion of valuable products than any other field in the world. The Appalachian field since its first discovery has produced 72 per cent of the entire output of the United States up to the close of 1902. In 1902 it produced 36.1 per cent of the entire production. The decline of this field has been gradual. The decrease in 1902 was 4.8 per cent, as compared with 7.4 per cent in 1901. The greatest decrease has been in the states of New York, Pennsylvania, and West Virginia. The work in 1902 was confined mostly to the development of the known pools, and no new areas were added to those already known. The southern portion of the field has been recently connected by a large pipe line system, reaching from Parkersburg, W. Va., to Lacy, Pickett county, Tenn., a distance of 270 miles, with several branch lines.

Table 16 shows the production of the several states in this field from 1889 to 1902. It is impossible to completely separate the outputs of New York and Pennsylvania, as some of the fields extend across the boundary, and are thus in both states. The regularity in the output of this field for the last twelve years is noticeable, as shown in the table of total production.

TABLE 16.—*Production of petroleum in the Appalachian oil field, by states: 1889 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States," 1902.]

[Barrels of 42 gallons.]

YEAR.	Total.	Pennsylvania and New York.	West Virginia.	Southeastern Ohio.	Kentucky and Tennessee.
1889	22,355,225	21,487,435	544,113	318,277	5,400
1890	30,073,307	28,458,208	492,578	1,116,521	6,000
1891	35,848,777	33,009,236	2,406,218	424,323	9,000
1892	33,432,377	28,422,377	3,810,086	1,193,414	6,500

1894	30,783,424	19,019,990	8,577,624	3,184,310	1,500
1895	30,960,639	19,144,390	8,120,125	3,694,624	1,500
1896	33,971,902	20,584,421	10,019,770	3,366,031	1,680
1897	35,230,271	19,262,066	13,090,045	2,877,838	322
1898	31,717,425	15,948,464	13,615,101	2,148,292	5,568
1899	33,068,356	14,374,512	13,910,630	4,764,934	18,280
1900	36,295,433	14,559,127	16,195,675	5,478,372	62,259
1901	33,618,171	13,831,996	14,177,126	5,471,790	137,259
1902	32,018,787	13,183,610	13,513,345	5,136,501	185,331

This table shows a decrease in the production in 1902, as compared with that of 1901, of 1,599,384 barrels, the equivalent of 4.8 per cent, which was greatest proportionally in southeastern Ohio. There were 5,591 productive wells drilled in both 1901 and 1902, and only 31 more dry holes drilled in the latter year than in the former. The only division showing an increase was Kentucky and Tennessee.

The well records for the Appalachian field are shown in Tables 17 and 18.

The total number of dry holes, or those that were destitute of petroleum in paying quantities, in the Appalachian field in 1902 was 2,131. This leaves 5,591 productive wells and shows that 72.4 per cent were productive and 27.6 per cent dry. The number of dry holes drilled in 1901 was 2,118, and there were 5,591 productive wells—the exact number credited to 1902 also. The proportion of productive and dry wells was 72.5 per cent and 27.5 per cent, respectively.

TABLE 17.—TOTAL NUMBER OF WELLS COMPLETED IN THE APPALACHIAN OIL FIELD, BY DISTRICTS: 1892 TO 1902.

[1] Barrels of 42 gallons. [2] Average.

Appalachian, Lima-Indiana, and all other fields.—Table 19 gives the production of the Appalachian, Lima-Indiana, and all other fields from 1896 to 1902, by years, and the percentage each is of the total. It also gives the average value of the production by years and the average price per barrel at which it was marketed.

One of the interesting conditions revealed is the regularity of the combined production of the Appalachian and the Lima-Indiana fields for the last five or six years; another is the very remarkable increase in the combined production of all other fields, which in 1896 amounted to but 2.84 per cent of the whole, but which was increased to 19.94 per cent in 1901, and to 37.62 per cent in 1902. The value of the petroleum and natural gas marketed in 1902 was greater than in previous years. In 1900 there was the largest production of higher priced grades of petroleum.

The value of natural gas marketed during the several years and the combined value of petroleum and natural gas are also given, for the reason that they are so intimately associated.

The largest production of natural lubricating petroleum is from the Franklin district, Pa. The other districts in the United States which produce natural lubricating petroleum are Petroleum and Volcano, in West Virginia; Mecca and Belden, in Ohio; and Salt Creek, in Wyoming. In 1902 the entire production amounted to 71,603 barrels, valued at $278,517.

TABLE 19.—PRODUCTION OF PETROLEUM IN THE APPALACHIAN, LIMA-INDIANA, AND ALL OTHER FIELDS, PERCENTAGES OF EACH, VALUE PER BARREL, AND THE VALUE OF PETROLEUM AND NATURAL GAS, SEPARATE AND COMBINED: 1896 TO 1902.

The value of the lubricating petroleum produced in Wyoming has for several years been $7 per barrel. The general character of the natural lubricating petroleum produced in West Virginia is similar to that produced at Franklin, Pennsylvania.

The production of the Franklin district for 1902 was 50,555 barrels, which was less than that of 1901 by 4,607 barrels.

There has been a gradual decline in this field since 1899, when the total yield was 61,085 barrels. The price received in 1902—$3.94—was slightly less than in 1901, when it was $4.

The following group of tables gives the runs or receipts, the shipments or deliveries, and the stocks of crude petroleum reported by the pipe lines in the Appalachian and Lima-Indiana fields for a series of years. Table 21 gives, in detail, the pipe line runs in the Appalachian field from 1888 to 1902, inclusive, and Table 22 the totals of the pipe line runs in the Appalachian and Lima-Indiana fields.

Table 23 shows the shipments in the Appalachian and Lima-Indiana fields, and Table 24 the stocks of petroleum in the same for the years 1894 to 1902, inclusive.

The fields in Kansas, Texas, and California and elsewhere are not so well supplied by pipe line companies, and the petroleum is transported mostly by private pipe lines, often owned by the producing company.

It will be seen from the preceding tables that for the year 1902 the combined runs for the Appalachian and Lima-Indiana fields were 51,388,553 barrels, which amount does not vary greatly from the average for the past eight years, though a slight decline was recorded in 1902 as compared with 1901. There are some few deliveries to refineries direct from the field and some petroleum loaded in tank cars that are not included in the pipe line reports.

The shipments which represent the deliveries from both these fields to the refineries and other consumers were quite large in 1902, amounting to 57,283,160 barrels, an increase of 3,040,919 barrels over those of 1901. As the shipments were larger than the production, the increase was made up from the stocks which had been accumulated by the pipe line companies.

The Appalachian and Lima-Indiana stocks on hand at the close of 1902 amounted to 23,048,050 barrels, showing a decrease for these fields of 4,347,748 barrels as compared with the amount at the close of 1901. These stocks are stored in large iron tanks at a number of localities, generally near the pumping stations of the main pipe lines.

The stocks in the fields are held principally by the large pipe line companies, who have, in nearly all cases, purchased the crude petroleum. There is also a varying amount of stock held by the original producers at their wells.

In the states of Texas and California, besides the stock in the hands of the producers and refiners, there are a number of individuals, companies, and railroads who own their tankage. The estimated stock in these and other states and territories, as well as in the Appalachian and Lima-Indiana fields, is shown in the following table:

TABLE 25.—*Stocks of petroleum held in the several fields, states, and territories at the close of 1902, 1901, and 1900.*

[Barrels of 42 gallons.]

FIELD.	1902	1901	1900
Total	36,168,050	32,090,798	29,350,476
Stocks in the Appalachian field[1]	5,741,624	9,635,492	13,475,548
Stocks in the Lima-Indiana field[2]	17,306,426	17,760,306	14,988,928
Stocks in Kansas (estimated)	210,000	70,000	60,000
Stocks in Colorado (estimated)	100,000	80,000	60,000
Stocks in Texas (estimated)	7,650,000	1,725,000	6,000
Stocks in California (estimated)	4,800,000	2,800,000	750,000
Stocks in Louisiana (estimated)	320,000	.....	.....
Stocks in all other states and territories[3]	40,000	20,000	10,000

[1] The Appalachian field includes New York, Pennsylvania, West Virginia, Kentucky, Tennessee, and the southeastern portion of Ohio.

[2] The Lima-Indiana field includes Indiana and northwestern Ohio.

[3] Includes Indian Territory, Oklahoma, Wyoming, Michigan, Missouri, and Illinois.

Stocks of Pennsylvania or Appalachian crude petroleum have decreased since the close of 1891. In that year there were 16,457,089 barrels of what is known as Pennsylvania oil, held in tanks, principally in Pennsylvania, and smaller amounts in West Virginia and Ohio, as compared with 5,741,624 barrels held at the close of 1902. In the Lima-Indiana field there were 22,103,705 barrels, principally in Ohio, making a total stock for the two fields of 38,560,794 barrels in 1891, as compared with 23,048,050 barrels at the close of 1902. Of the latter amount 5,741,624 barrels were Appalachian petroleum and 17,306,426 barrels Lima-Indiana petroleum. The success in refining the petroleum from the Lima-Indiana field has greatly increased the production of the higher grade of illuminating petroleum and enabled the refiners to supply their home consumers and furnish an increasing quantity for the export trade.

The following table gives the average yearly price of all the grades of petroleum from 1889 to 1902:

TABLE 26.—*Average yearly price of all the petroleum produced: 1889 to 1902.*

[Barrels of 42 gallons.]

YEAR.	Average price (cents).	YEAR.	Average price (cents).
1889	76.62	1896	95.90
1890	77.17	1897	67.70
1891	56.25	1898	79.80
1892	51.33	1899	113.20
1893	59.75	1900	119.10
1894	72.00	1901	95.70
1895	108.88	1902	80.20

The average prices shown in the following table cover the ordinary grades of petroleum. They do not include special oils, such as the lubricating oils from the Franklin district, nor those from the Petroleum and Volcano districts of West Virginia, nor those from the Mecca-Belden district of Ohio, but only those, such as Pennsylvania oil, used chiefly for the production of illuminants.

TABLE 27.—*Range of prices paid for petroleum in the Appalachian oil region by the Seep Purchasing Agency during 1902.*

December 12	1.66	1.51	1.31	1.38
December 31	1.69	1.54	1.34	1.41

In some of the districts oil is worth more than ordinary Pennsylvania oil, and in some districts it is worth less. This is owing to the fact that the production of some districts furnishes a larger percentage of illuminating oil and of by-products. Petroleum that has remained in tanks at the wells for a long period loses a percentage of its illuminating properties and is worth less than what is known as fresh oil, or petroleum recently produced at the wells.

The great volume of trade is controlled by the prices under the name of Pennsylvania oil, which includes nearly all the oil sold in New York, nearly all of that sold in Pennsylvania and West Virginia, and a large proportion of the ordinary Appalachian petroleum sold in Ohio.

In the following table are given the average monthly prices during 1901 and 1902 of crude petroleum produced in the various districts of the Appalachian oil regions in which special prices are paid. It is considered that the bulk of the crude petroleum is sold at prices slightly greater than the average price per month.

Average of North and South Lima	0.88¼			0.86		

The North Lima is separated from the South Lima field by an east-and-west line passing through the southern portion of the town of Fostoria, Ohio. This division is made owing to the lighter gravity of North Lima petroleum and the larger percentage of the more valuable products secured from it. The production of the Indiana field is of the same grade as the South Lima petroleum and commands the same price.

In the following table there is shown the fluctuations in prices for the various grades of Lima oil in 1902. The dates are those on which changes in prices were made.

TABLE 30.—*Fluctuations in prices of Lima (Ohio) and Indiana crude petroleum: 1902.*

[1] North Lima. [2] South Lima.

REVIEW OF THE INDUSTRY BY STATES AND TERRITORIES.

Alaska.—There are three known localities along the west coast of Alaska in which there are surface indications of the existence of natural petroleum. The first begins a short distance northwest of Cape Yaktag, 450 miles northwest of Sitka and just west of Mt. St. Elias. There are numerous natural springs of petroleum and water extending for a distance of 25 miles farther northwest, in a line parallel to that of the coast. For this distance there is a continuous line of foothills 500 to 600 feet in height, cut by numerous streams. Along the streams, near the axis of this uplift, there are numerous petroleum indications. Seventy-five miles farther west along the coast line, between Cape Suckling and Cape Martin, near the waters of Catella bay, there are also springs of petroleum associated with sulphur water and natural gas a short distance inland. Still farther inland there are seams of bituminous coal from 3 to 8 feet in thickness and of superior quality. This section is generally known as the Kayak region, as it is nearly opposite Little Kayak Island. Seventy-five miles farther north, also on the mainland opposite Kochernak bay, at the mouth of Cooks inlet, there are also some surface indications of petroleum.

One of the original discoverers of these surface indications was Mr. R. C. Johnson, who ran across them while exploring the numerous small creeks along the ocean for gold. A company he organized succeeded in getting down a well late in the summer of 1902, which, at 365 feet, gave very promising results. It was located on one of the small streams entering Catella bay from the east on a low divide extending toward Point Hay, where there were abundant surface exposures and small feeders of petroleum constantly coming to the surface. The following is a record of the well as reported by the company:

Log of well east of Catella bay, Kayak district, drilled in 1902.

FORMATION.	Feet.
Total	366
6 feet surface drift	6
10 feet decomposed shale	16
140 feet light colored shale	156
18 feet fine grained sandstone	174
One-half foot coal contained in the sandstone	174½
190 feet dark shale, very hard	364½
One-half foot quartz containing iron pyrites, and contained in the shale	365
1 foot oil sand and flow of oil	1
Length of 12-inch casing	220
Length of 9⅝-inch casing	310

Numerous small showings of petroleum and natural gas were encountered as the drill proceeded downward. At 366 feet a large quantity of oil was developed, which is reported to have flowed, and the well is said to have continued to flow until capped.

California.—Although there were fewer wells drilled in California in 1902 than in 1901, the production reported showed a large increase over that of the previous year, which is partially due to the large quantity held from the previous year at the wells owing to the lack of transportation. The production in 1902 placed this state third in the order of output; only Ohio and Texas produced greater quantities. There is no question that if all the facilities for transportation had been supplied the production would have been largely increased.

Under these conditions the production in 1902 was 13,984,268 barrels, produced by 2,574 wells. The value of the production was $4,873,617. The average price was 34.8 cents per barrel. There were stored at the close of 1902 nearly 4,000,000 barrels of petroleum awaiting transportation.

The completion of the pipe line must have the effect of relieving this condition in the Kern river field and of delivering large quantities of petroleum to Point Richmond, on San Francisco bay, where it will find a ready market as fuel. This is especially desirable, as there is a scarcity of coal on the Pacific coast.

The importation of coal fell off more than 25 per cent during 1902. The number of large manufactories and railroads using this liquid fuel almost exclusively is rapidly increasing, so that the indications are that the importation of coal must suffer a still greater decrease, and the introduction of petroleum as a fuel must become general. There can be at least 25,000,000 barrels annually disposed of as fuel in California alone. It has been demonstrated that the use of cheap fuel is one of the chief aids to commercial supremacy, and with the development of this and other natural advantages California may become one of the prominent manufacturing states.

There were 425 wells completed during 1902, but of this number 102 were dry or unproductive, leaving 323 productive wells. The total number of pumping wells was 2,539 and of flowing wells, 35.

Wells were drilled in 18 counties in California during 1902, from the extreme northern county of Humboldt to San Diego on the south. The counties in which the greatest production was secured are, in the order of their output, Kern, Los Angeles, Orange, Fresno, Ventura, Santa Barbara, and San Mateo. Of the total production, 69.4 per cent came from Kern county, 13.9 per cent from Los Angeles county and the remaining 16.7 per cent from the remaining productive counties.

In drilling the many wells in numerous portions of the state only one new pool was discovered—in Santa Clara, near Sargent Station—where, at a depth of 800 feet, a producing sand was found which yielded 80 to 90 barrels per day. There were a number of test wells drilled near Half Moon bay, in San Mateo county, but these produced only a limited quantity of a high grade crude petroleum. There is a great variety of crude petroleum produced in California, ranging from a black, tarry liquid of 11° Baumé to water-white naphtha. The great proportion is a heavy, dark petroleum of about 16° Baumé eminently fitted for fuel purposes.

Bakersfield is the largest producing district in California. It is generally known as the Kern river field, and is located in Kern county, a few miles north of the city of Bakersfield. There are two other fields to the south, known as the Sunset and McKittrick pools, but these are as yet insignificant in production when compared with the Kern river field. The petroleum produced in this latter field varies from 11° to 17° Baumé. There is a remarkable bed of sand, ranging from 200 to 500 feet in thickness, found in most of the wells, and considerable sand and some water are found in the crude petroleum. This is separated by allowing the petroleum to stand in large ponds, although in some instances it is necessary to heat the petroleum to secure a complete separation. There is, no doubt, a large quantity of petroleum in this pool, which can be taken out when the conditions of transportation have become more favorable, as during 1902 many of the wells were shut in for a portion of the time.

The Los Angeles field is one of the original fields in this state and has produced a large quantity of fuel petroleum for a number of years. There was a slight decline in the production of 1902 as compared with that of 1901. The wells in this field range from 600 to 1,200 feet in depth and vary in production from 2 to 25 barrels per day. The petroleum is black, with a gravity varying from 15° to 17° Baumé. Recently a pipe line has been constructed connecting the Whittier pool with Los Angeles. There is also a producing field at Newhall, at the head of the Santa Clara canyon, in this county, which yields a superior grade of petroleum.

Some very good wells have been secured in Orange county at Fullerton, at Brea canyon, and elsewhere in the vicinity. A few of these wells were drilled to a depth of 2,400 feet, and the production at first reached as much as 1,000 barrels per day. The Whittier pool, in Los Angeles county, lies just northwest of the Fullerton pool. These pools produce a petroleum of high grade, which is in demand for refining and for which a high price is paid.

The Coalinga field, on the east flank of the Coast Range in Fresno county, was opened up in 1897. Most of the petroleum produced in this field ranges from 22° to 38° Baumé, although there is some petroleum as heavy as 11° Baumé. In the northeastern portion of the field the gravity of the production ranges from 20° to 28° Baumé. It is suitable for refining and is in demand as an enricher of manufactured gas.

Ventura county continued to produce petroleum in a comparatively small way along the Santa Clara valley to the south. There is considerable variation in the character and gravity of the petroleum produced. A very light petroleum of about 35° Baumé is found in Pico canyon near the Los Angeles county line.

Operations were active in Santa Barbara county in 1902. A large production was secured on Los Alamos creek, which locality has been operated successfully for several years. A well with a capacity of 200 barrels was found near Lompoc. Summerland district is in this county, but was not actively operated during 1902, and has declined in production.

The problem of transportation from the California oil fields has not been fully solved. The oil development of the state has been much retarded by the lack of facilities for getting the oil to market. Most of the production is within reach of the railways by short pipe lines, but there has been a deficiency of cars to meet the demands, and consumers have hesitated to

adopt oil as fuel because of the uncertainty of getting a supply when needed.

An 8-inch pipe line is being constructed from the Kern river district to a refinery at Point Richmond, on San Francisco bay, which eventually will have branches to the important oil producing localities in the San Joaquin valley. A branch to the Coalinga field is now in process of construction. The main pipe line will be 278 miles in length with 10 pumping stations, and the oil will be heated to permit its easy pumping. The completion and operation of this pipe line are matters of very great importance to the industry of the state. A railway, chiefly for the transportation of crude oil, is projected from the Sunset district to tide water at Port Harford, but at the close of 1902 little progress had been made toward its construction.

Tankage supply stations have been established in the Hawaiian Islands, and large tank steamers are now running to the islands from San Francisco and southern California ports. Large supply stations are also being installed at various points along the coast as far north as Washington, and these will be supplied by the railways or by ocean transit as will be most convenient.

The chief use of California petroleum is as fuel, and the market for it was gradually extended during 1902.

The railways of the state are adopting it as rapidly as possible. The Southern Pacific Railway has established a large amount of tankage on its line at different points. Both the Southern Pacific and the Atchison, Topeka and Santa Fe railways are the owners of tracts of oil lands from which part of their supply is drawn. The use of the heavy oils for improving roads is increasing.

The price of California oil during 1902 was low, but some advance took place toward the close of the year. Large contracts for the delivery of oil at the wells for a period of five years, however, were made at the rate of 20 cents a barrel. This price applied to the heavier oils of the Kern river and McKittrick districts. Lighter oil produced in the southern part of the state commanded as high as $1.00 and $1.20 a barrel where the quality was such as to permit refining into illuminating oils.

During the year the number of refineries in the state increased from 11 to 33. Most of them were small and designed more particularly for the production of asphalt from the heavy oils, which yield from 40 to 50 per cent of this material. The distillates obtained in this way are used largely for domestic fuel, for gas making purposes, and, to a slight extent, for spraying fruit trees. The largest installation for refining California oils is at Point Richmond, near San Francisco. In the following table is shown the production of petroleum in California by counties for the years 1897 to 1902:

TABLE 32.—*Production of crude petroleum in California, by counties: 1897 to 1902.*

[Barrels of 42 gallons.]

COUNTY.	1902	1901	1900	1899	1898	1897

[1] San Mateo.

Colorado.—There was a considerable amount of new work accomplished in Colorado during 1902, although the product was but 396,901 barrels, a decrease of 63,619 barrels as compared with 1901. The production of the Boulder pool was only 11,800 barrels. Its quality was superior to any other petroleum found west of the Mississippi river, and its gravity when fresh was 42.5° Baumé.

The new Boulder field was partially opened up in 1901 by the McKenzie well, which found petroleum at a depth of 2,720 feet and was the cause of the drilling of a number of deep wells in this new field. These, however, produced only a limited quantity of high-grade petroleum. There were 48 wells drilled in the state, 28 of which were dry. The total number of producing wells was 77, and the number abandoned during the year, 6. There were 60 tanks at wells, with a combined capacity of 41,579 barrels.

An important deep well was drilled in the old Florence field south of the city, which at a depth of 3,650 feet found a pay streak never before reached by any of the wells in that field. The strata in which the petroleum is found stored in this field, and also in the Boulder field, are considered to belong to the Fort Pierce group of the Montana Cretaceous. The Florence field furnished nearly 98 per cent of the state's production in 1902.

The petroleum is of a dark green color, with a gravity of from 31° to 32° Baumé, and in refining gives a fair yield of the more valuable products. The production in 1902 sold for $484,683, an average of $1.22 per barrel being secured.

Illinois.—The production of petroleum in this state, although extending over a period of nearly fifteen years, has been insignificant. Even the small production secured seems to be growing smaller. There is a probability, however, that the state may yet produce sufficient petroleum to become of significance as a producer.

Nearly all of the petroleum comes from Litchfield, Montgomery county, and is used locally for lubricating

purposes. Its gravity is 22° Baumé. The wells are from 640 to 670 feet in depth. There is a small production from shallow wells at Washington, Tazewell county. It finds a sale as lubricating petroleum, the production, valued at $5 per barrel, amounting to $1,000. In October, 1901, petroleum was reported to have been found in small quantities 6 miles west of Canton, Fulton county, and also in the town of Herscher, Kankakee county. The production of the state since 1889 has been as follows:

TABLE 33.—*Production of petroleum in Illinois: 1889 to 1902.*

[Barrels of 42 gallons.]

YEAR.	Quantity.	YEAR.	Quantity.
Total	6,576	1895	200
		1896	250
1889	1,460	1897	500
1890	900	1898	360
1891	675	1899	360
1892	521	1900	200
1893	400	1901	250
1894	300	1902	200

Indiana.—The production in this state comes almost entirely from one horizon, known as the Trenton limestone. There are probably 28 barrels of salt water pumped for each barrel of petroleum produced.

A number of wells that were formerly natural gas producers have been drilled deeper and have found petroleum in paying quantities. It is a field of easy access, and is abundantly supplied with facilities for transporting supplies, as well as with pipe lines, for marketing the petroleum. The production in 1902 was 7,480,896 barrels of crude petroleum, valued at $6,526,622. This is a gain of 1,723,810 barrels in quantity, and $1,703,796 in value over 1901, the increase amounting to 29.9 per cent in quantity and 35.3 per cent in value. Indiana was the only state in the northeastern portion of the United States that gave an increased production in 1902.

The most active operations during 1902 were in Grant county, one-third of the new wells in the state being drilled in this county, adding a considerable new and rich territory to the known productive area of the state. The section near Marion once famous for large natural gas wells is now important as a petroleum producing region. The exhaustion of the gas enabled operators to drill the wells deeper, and results have been remarkably successful. The counties of Adams, Blackford, Delaware, Huntington, Jay, Madison, Randolph, and Wells were all more or less conspicuous for new wells and increased production during the year. In addition to the production from the regular limestone strata of the Trenton horizon, there are a number of small pools in newer horizons that have produced small quantities of petroleum, but no very successful wells were discovered, although there was a small production in Dubois, Jasper, Martin, and Vigo counties.

The following table gives the production of petroleum in Indiana from 1891 to 1902:

TABLE 34.—*Production of petroleum in Indiana: 1891 to 1902.*

YEAR.	Quantity (barrels).	Total value at wells of all oil produced, excluding pipeage.	Value per barrel.
1891	136,634	$54,787	$0.40
1892	698,068	260,620	0.37
1893	2,335,293	1,050,882	0.45
1894	3,688,666	1,774,260	0.48
1895	4,386,132	2,811,444	0.64
1896	4,680,732	2,954,411	0.63
1897	4,122,356	1,880,412	0.45⅝
1898	3,730,907	2,214,322	0.59⅜
1899	3,848,182	3,363,738	0.87⅜
1900	4,874,392	4,693,983	0.96⅜
1901	5,757,086	4,822,826	0.83⅞
1902	7,480,896	6,526,622	0.87⅛

The whole number of producing wells in 1902 was 8,224, of which 8,223 were pumping and 1 flowing. There were 2,932 wells drilled, of which 443 were dry and 2,489 were producers. The abandoned wells numbered 772. The number of receiving tanks at the wells was 2,568, having a combined capacity of 592,172 barrels.

Kansas.—This state was the scene of a large amount of development during 1902. The main portion of the production was secured in Allen, Neosho, and Wilson counties. Several new pools were opened up, and the Chanute pool opened in 1901 was greatly extended. No very large gushers were developed, yet a large percentage of the wells drilled were profitable producers. The depth of the wells in the Kansas field is not great, ranging from 750 to 900 feet, and their production runs from 10 to 50 barrels.

The petroleum and natural gas developed in southeastern Kansas are generally found in a dark sand from 15 to 25 feet in thickness, almost immediately above the Mississippian limestone. It is not a persistent stratum, but is more or less a local deposit in the Cherokee shales. In other sections of the state these shales carry deposits of bituminous coal. There is a general dip to the west, which soon carries this formation too deep to be reached by ordinary methods of drilling. Indications point to the probability of Kansas becoming a large producer of petroleum, and in 1902 its production increased 85.2 per cent; the pipe lines and transportation companies could not take care of it. Early in 1903 a pipe line was constructed, connecting the refinery at Neodesha with the newly developed field of Chanute and Humboldt.

The total number of wells drilled in the state of Kansas during 1902 was 282. Of this number, 245 were productive and 37 dry holes. The total number of pumping wells was 367, and the flowing wells numbered 52. There were 14 wells abandoned. There were 304 tanks at the wells, with a combined capacity of 43,238 barrels.

The total production of oil in Kansas, so far as records have been obtained, is as follows:

TABLE 35.—*Production of petroleum in Kansas: 1889 to 1902.*

[Barrels of 42 gallons.]

YEAR.	Quantity.	YEAR.	Quantity.
1889	500	1896	113,571
1890	1,200	1897	81,098
1891	1,400	1898	71,980
1892		1899	69,700
1893	18,000	1900	74,714
1894	40,000	1901	179,151
1895	44,430	1902	331,749

The value of the petroleum produced in Kansas in 1902 was $292,464, an average of 88 cents per barrel. The average price per barrel received in 1901 was 84 cents.

Kentucky.—The events of 1902 were of considerable importance, the extensive pipe line system being completed from Parkersburg, W. Va., to Somerset, near the southern boundary of the state. There are also branch lines from the main trunk line to Barbourville, Ragland, and the Prestonsburg fields. The entire length of the trunk line from where it crosses the state line from West Virginia to the Tennessee state line is 190 miles. There are also 85 miles of branches, making a total of 275 miles of pipe line. A very considerable amount of development work was done in Kentucky during 1902 in the counties of Allen, Barren, Bath, Clark, Clay, Clinton, Cumberland, Estill, Knox, Lewis, Lincoln, Menifee, Morgan, Powell, Pulaski, Rowan, and Wayne. The production of petroleum in 1902 was 248,950 barrels, valued at $172,837, an average of 69 cents per barrel, a gain of 81.4 per cent in quantity over the production in 1901.

Louisiana.—The presence of petroleum in this state has been known for a number of years, as there were numerous localities in the southwestern portion where springs carrying a proportion of petroleum were known to exist. The developments in 1901, a few miles to the southwest, were the incentive to a larger amount of prospecting in various portions of the state during the years 1901 and 1902. There was some slight production in this state during the year 1901, but there were no sales, and no value could be given. The most successful development was near Jennings, 90 miles east of Beaumont, Tex., and 190 miles west of New Orleans. There were also a number of productive wells drilled at Welsh, 12 miles west of Jennings, and a number of wells in which there were indications of petroleum were drilled at Calcasieu, Lake Charles, Crowley, Lafayette, and Sulphur. In several other localities there were outbursts of natural gas accompanied by a slight showing of petroleum. The most important field discovered in the latter part of 1901 was located 6 miles northeast of Jennings, in Acadia parish.

At a depth of 1,822 feet one well found a considerable amount of petroleum in a bed of loose sand. It flowed spasmodically considerable quantities of petroleum, mixed with more or less sand, to a considerable height above the derrick. Owing to caves and several unforeseen conditions this well had to be abandoned at the close of 1902. In this pool in the same stratum producing the petroleum a strong gas pressure was encountered which threw out large quantities of loose sand, frequently clogging up the casing and thereby shutting off the flow. Some of these difficulties were overcome by the insertion of perforated casing in the bottom. Little or no solid formation is found in the drilling of these wells. The petroleum is about 26° Baumé, and is said to be somewhat superior to that produced in the Beaumont and Sour Lake pools.

About 12 miles west of Jennings the Welsh pool is located. There are indications that a considerable area of productive territory would be found in this locality. The same difficulty presented by beds of loose sand associated with petroleum and natural gas is encountered in this field. The Jennings and Welsh fields had been connected by pipe line with both railroad and tide water transportation, and a large amount of the product has been marketed as fuel petroleum.

Missouri.—There has been a small production of petroleum in this state since 1889, the product being secured from a shallow well located in Bates county, near the town of Merwin. It is heavy and dark in color, and finds sale as a lubricating petroleum.

During the year 1902 seven shallow wells, from 340 to 490 feet in depth, were drilled at Belton, in Cass county, and a small quantity of lubricating petroleum was secured. The production in this field, although insignificant in 1902, showed an increase over the previous year.

Michigan.—The production of petroleum in Michigan has been somewhat irregular since it was first developed in a small way in 1900 near Port Huron. The principal source of petroleum is the Corniferous limestone, and the pay rock, 13 feet in thickness, is found at a depth of 524 feet. This same stratum is productive to the east, in Canada.

Montana.—In the northern part of this state, near the Canadian border and east of the Flathead river, there are a number of indications of petroleum in natural springs. North of this section, in Alberta, Canada, a recent strike of petroleum is reported on the waters of the Kootenai river. In the southeastern portion of this state, in Carbon and Sweet Grass counties, some petroleum indications are reported. Three wells were recently completed in Carbon county, in which, however, only a very small quantity of petroleum was secured.

Nevada.—Although several wells were drilled in this state during 1901 and 1902 no production of petroleum was secured. Several wells drilled in the vicinity of

Elko encountered sand and shales similar to those in which petroleum is found in other localities, but no petroleum was developed.

New Mexico.—There are indications of petroleum and asphaltum deposits scattered over a large area in New Mexico, but nothing yet has been developed in the way of productive wells. There are a considerable number of natural showings of petroleum in San Juan county, and indications are reported in the Salado region near Santa Rosa in Guadalupe county, as well as in Colfax, Eddy, Lincoln, Otero, and Union counties, all of which remain to be tested.

New York.—For the sake of conducting the business of collecting the crude petroleum in a convenient manner, and keeping the same grade of petroleum together, the producing areas in the several states have been divided into districts. These districts are not always separated by state lines, as in several instances a producing area extends from one state into another, and the complete separation of the products of the different states is more or less difficult. This is particularly so in the Appalachian field.

The productive area of petroleum in New York is located in the southwestern portion of the state, and embraces the most northeastern part of the Appalachian field. There are two districts, one known as the Allegany district, which is entirely within the state, and the other as the Bradford district, which extends as a continuous producing area into Pennsylvania. The entire production of petroleum in 1902 was 1,119,730 barrels, valued at $1,530,852, an average of $1.367 per barrel. The number of barrels produced in 1902 showed a decrease of 7.2 per cent, yet the value of the production increased $70,844, as compared with 1901. During 1902, 8,443 wells were reported by 2,123 companies or individuals. There were 626 wells drilled, of which 95 were dry and 531 productive, and 170 wells were abandoned. There were 8,178 pumping wells operated during 1902.

Ohio.—Since 1895 Ohio has produced more petroleum than any other state. In the southeastern part of the state petroleum has been known to exist for many years. The field in the northwestern portion was developed in 1885. There are two well-defined grades of petroleum produced. That in the southeastern portion is similar to the petroleum produced in Pennsylvania and West Virginia; that in the northwestern portion is a peculiar variety of petroleum, containing a considerable percentage of sulphureted hydrogen. For years it was extensively used as a fuel petroleum, as the sulphureted hydrogen imparted a very disagreeable odor to the refined products. It was only after several years that it was successfully refined.

The total production of Ohio in 1902 was 21,014,231 barrels, valued at $20,757,359. Of this amount there were 5,136,366 barrels produced in the southeastern portion, which is a part of the Appalachian field, and 15,877,730 barrels produced in the northwestern portion, known as the Lima-Indiana field. There was also a very small amount of lubricating petroleum produced in this state, in the Mecca and Belden fields, amounting to 135 barrels. This commanded a high price. The value of petroleum produced in the southeastern portion of the state was $6,471,821. That produced in the Lima-Indiana portion was valued at $14,284,072. The output of the Mecca and Belden pools was valued at $1,466. Ohio has produced 24.4 per cent of all the petroleum that the United States has produced since the beginning of the petroleum production. The total number of wells completed in the state during 1902 was 5,313. Of these 3,532 were in the Lima-Indiana field and 1,781 in the southeastern field. Of the total number 894 were dry and 4,419 productive, which includes 3 flowing wells. There were all told 39,056 producing wells, and 2,533 wells were abandoned.

The total quantity and value of crude petroleum produced in Ohio in all fields during 1902 and 1901 are shown in the following table:

TABLE 36.—*Total quantity and value of crude petroleum produced in Ohio: 1902 and 1901.*

DISTRICT.	1902			1901		
	Quantity (barrels).	Value.	Price per barrel.	Quantity (barrels).	Value.	Price per barrel.
Total	21,014,231	$20,757,359	$0.99	21,648,083	$20,533,571	$0.95
Lima	15,877,730	14,284,072	0.89	16,176,293	13,911,612	0.86
Southeastern	5,136,366	6,471,821	1.26	5,470,850	6,619,342	1.21
Mecca-Belden	135	1,466	10.85	940	2,617	2.78

The gross output of the state has exceeded 21,000,000 barrels for the last four years. It will be seen that during 1902 there was a decrease in the production of 633,852 barrels as compared with 1901. In 1901 there was a decline from 1900 of 714,147 barrels.

The production of the Lima (Ohio) district since 1889 has been as follows:

TABLE 37.—*Production of petroleum in the Lima (Ohio) district: 1889 to 1902.*

YEAR.	Quantity (barrels).	YEAR.	Quantity (barrels).
1889	12,153,189	1896	20,575,138
1890	15,014,882	1897	18,682,677
1891	17,315,978	1898	16,590,416
1892	15,169,507	1899	16,377,174
1893	13,646,804	1900	16,884,358
1894	13,607,844	1901	16,176,293
1895	15,850,609	1902	15,877,730

The production of the southeastern Ohio district for the same period is given in the following table:

TABLE 38.—*Production of petroleum in the southeastern Ohio district: 1889 to 1902.*

YEAR.	Quantity (barrels).	YEAR.	Quantity (barrels).
1889	317,037	1896	3,365,365
1890	1,108,334	1897	2,877,193
1891	422,883	1898	2,147,610
1892	1,190,302	1899	4,764,135
1893	2,601,394	1900	5,475,589
1894	3,183,370	1901	5,470,850
1895	3,693,248	1902	5,136,366

The production of the Mecca-Belden lubricating oil districts of Ohio has decreased from 2,283 barrels in 1900 to 940 barrels in 1901 and 135 barrels in 1902. This is the highest grade natural petroleum produced in the United States, but the demand for it is very small and operations are at a standstill. The average price for the Mecca oil in 1902 was $15.91 per barrel, or about 38 cents per gallon. This is much greater than the price of the manufactured article, which has in a measure driven this natural product out of the market.

Oklahoma.—There are many natural petroleum seeps in this territory, but nothing in the way of established production of petroleum was reported for 1902. Some oil is produced quite near the boundary line of Indian Territory. In addition numerous springs and wells have indications of petroleum, and liquid and solid asphalt have been found in shafts and water wells. Guthrie, Lawton, Fort Sill, Richards, and Granite all have a number of natural vents, showing both petroleum and natural gas, and in all probability a few years will see this territory placed on the list of regular producers.

Oregon.—A number of test wells were drilled in Lane, Douglas, Jackson, and Wasco counties, none of which found petroleum or natural gas. In Josephine county there are several springs reported on which a film of petroleum collects.

Pennsylvania.—Of the entire production of petroleum in the United States since the first discovery of the oil in 1859, Pennsylvania has produced one-half of the entire output. The production of petroleum in Pennsylvania in 1902 was 12,063,880 barrels, amounting to 13.5 per cent of the total, valued at $15,266,093. The number of wells producing in that year was 37,806. The number drilled was 3,034, of which 2,275 were productive and 759 were dry. The abandoned wells numbered 1,879. There were 20,323 tanks of varying sizes at the wells, with a capacity of 1,864,755 barrels.

The petroleum producing areas of Pennsylvania are divided into districts on the basis of quality of output and county lines. A district is in some cases subdivided into pools which produce similar grades.

The Bradford district is located in McKean county in the most northern portion of the state, a portion of it extending over into New York. It was formerly a very prolific region, nearly the entire area being underlaid by a productive sand 50 feet thick, but for several years it has shown the effect of drainage by a steadily decreasing output. In 1881 this district produced 23,000,000 barrels of petroleum. Its production for 1902 was 2,506,981 barrels.

The Gaines district is located in Tioga county, just east of the Potter county line. It is the most easterly district producing petroleum in the United States. Its production for 1902 was 24,881 barrels, which was 12,610 barrels less than that of the previous year. The wells in this district are known as "flashy"—that is, they produced a large amount when first opened up, but soon dropped off and became very small producers.

Clarendon and Warren district includes the western portion of McKean county, the eastern portion of Warren county, the northeastern portion of Forest county, and the northwestern portion of Elk county. In this district some of the finest petroleum produced in the United States is found, known as Tiona petroleum, which commands a higher price than the ordinary Pennsylvania variety. The Clarendon and Warren district proper produced 468,420 barrels in 1902, which is a gain of 63,987 barrels over the previous year.

The lower district contains the oldest wells in the Appalachian field, along the valley of Oil creek. Some of these wells have been producing over twenty-five years. The district includes a portion of Forest, Venango, Clarion, and Butler counties. There is a great number of wells of small production in this district. The production in 1902 was 4,754,979 barrels, which is a decrease of 100,070 barrels as compared with the previous year. Many deep wells were drilled in the new Speechley field, near the old Modac pool, in Butler county, and there were also a number of large wells secured in the Fourth sand near Middletown, which, however, rapidly declined.

In the Allegheny county district no new pools were developed in 1902. This district produced 1,376,212 barrels in 1902, which was a decline of 64,755 barrels as compared with the previous year. This district contained the famous McDonald pool, which in 1891 increased its production to 10,317,258 barrels.

The Washington county district produced 1,396,831 barrels in 1902, which was a gain of 96,432 barrels over the previous year. There were no new pools discovered, but several extensions of the older pools were developed.

Beaver county district produced during the year 1902 528,734 barrels. There was a decline of 270,544 barrels in 1902 compared with 1901.

Greene county district also showed a slight decrease in 1902, when the output amounted to 721,574 barrels against 771,708 barrels in 1901. All the wells drilled

in this section are from 2,400 to 3,000 feet in depth, which makes the drilling and operating expensive. A dry hole under such circumstances means a loss of between $6,000 and $7,000. Some of the older wells in this region are remarkable, on account of their continuous production, the decline being very slight during a series of years.

Franklin district is a subdivision of the lower district, and has long been celebrated for the production of the finest natural lubricating petroleum found in the United States. The production of this variety of petroleum is secured from the First sand, which has a thickness of about 50 feet. This stratum is at a comparatively shallow depth, and is associated with large quantities of salt water. Many of these wells produce only a few gallons of this superior grade of petroleum in a day. The production of this district in 1902 was 50,555 barrels, which showed a decline of 4,607 barrels when compared with the previous year.

The production of the Pennsylvania and New York fields for the years 1891 to 1902, inclusive, by districts, is shown in the following table, all of the districts being wholly within Pennsylvania, except Allegany and a portion of the Bradford district referred to under the head of New York:

TABLE 39.—PRODUCTION OF CRUDE PETROLEUM IN PENNSYLVANIA AND NEW YORK, BY DISTRICTS: 1891 TO 1902.

[Barrels of 42 gallons.]

Tennessee.—The production of petroleum in this state since 1896 has been secured in great measure from a remarkable well drilled on the Obey river in Fentress county. This well at a depth of 276 feet struck a deposit of petroleum which alone has produced nearly 40,000 barrels up to the close of 1902. It would seem that this well pierced a cavern either in the Clinton limestone or the upper Hudson river formation. The petroleum is of a light green color with a specific gravity of 0.846 or 35° Baumé. During 1901 the large tanks near this well were connected by a pipe line with the Slickford pool in Kentucky, a distance of 20 miles. During the year 1902 a few small wells were opened in the vicinity of this remarkable well which helped to increase the production in this state. There were a number of wells completed in Pickett, Fentress, and Sumner counties, several of which had a considerable showing of petroleum or natural gas; the greater portion, however, were destitute of petroleum in sufficient quantities to become paying wells. The numerous surface indications over a large area in this state have generally proved misleading. There seems to be an absence of an open, porous, continuous bed that is capable of furnishing a reservoir for the accumulation of petroleum. The wells that so far have proved to be producers, in greater or less amounts, seem to draw their supply from a crevice in the stratum or a cavity in the limestone formation.

Texas.—For a number of years the state of Texas produced an insignificant amount of petroleum from Sour Lake, Nacogdoches, and the San Antonio fields. Its remarkable output in 1902 placed it second in the list, next to Obio. The year 1896 was notable for the opening of the Corsicana petroleum field, in which a considerable quantity of a very valuable petroleum was discovered. This petroleum is rather dark in color and ranges from 38° to 40° Baumé. A few years later a refinery was erected at Corsicana, where almost the entire production has been successfully refined.

On January 10, 1901, a very remarkable well was

completed in southeastern Texas, about 4 miles south of Beaumont, in Jefferson county, and about 20 miles north of the Gulf of Mexico. At the close of 1902 there were some 120 wells producing in this locality. The producing area is confined to about 185 acres, on an elevation or mound which rises to about 15 feet above the general surface of the plain. The summit is nearly 40 feet above the level of the sea. The wells are usually slightly over 1,000 feet in depth, and originally were gushers. Some of them in the early history of the field produced as much as 75,000 barrels per day. Outside of this immediate locality described, nothing but dry holes have been developed, although some of these wells have been drilled to a depth of from 2,500 to 3,000 feet.

Probably no other event in the development of the petroleum industry in the United States created such a profound sensation as the opening up of this prolific territory near tidewater. The productive area near the original well during the summer and fall of 1901 and the early part of 1902 was crowded by a great number of wells, many of which were productive, although the output of the later ones was insignificant in comparison to the output of the earlier. The first well in this pool was located by Capt. A. F. Lucas, who was attracted to the locality by the existence of strong sulphur and acid springs and the presence of pure sulphur, together with a considerable outflow of natural gas. Two unsuccessful attempts had formerly been made to test this locality. A considerable amount of gas pressure in pockets was developed above the oil producing horizons, and this in some instances blew out great volumes of sand and water before it became exhausted.

During the latter portion of 1901 another large pool was partially developed at Sour Lake, 20 miles northwest of Beaumont, underlying the shallow wells that were originally drilled in this locality. In November of that year a well was completed to a depth of 1,500 feet which encountered more or less loose sand alternating with beds of gravel. At a depth of between 850 and 880 feet a deposit of sand was found which gave a large flow of hot sulphur water at a temperature of about 100° F., accompanied by some showing of petroleum. At a depth of 1,040 feet four distinct sands were encountered. These loose sands contained some petroleum associated with hot water, but no considerable quantity was developed.

About the middle of March, 1902, a gusher was opened up at a depth of 683 feet, after 40 feet of very promising oil sand had been penetrated; when the water became exhausted the well began to flow vigorously, accompanied by the outburst of loose sand, which on several occasions completely shut off the petroleum. By the use of casing with larger perforations than had previously been used, the inrush of loose sand was overcome, and many very productive wells were secured.

The gravity of petroleum produced in this region ranges from 22° to 23° Baumé, equal to a specific gravity of 0.92. The fresh oil gives a flash point at 120° F., while upon standing in a tank for some time the flash point is increased to 160° F. In the latter part of 1901 and the year 1902 a number of pipe lines were constructed reaching from Beaumont to Port Arthur and Sabine Pass. Two pipe lines were constructed from Sour Lake to Beaumont.

Twelve miles northwest of Sour Lake, in what was known as the Saratoga district, several productive wells of moderate capacity were drilled with promising indications of an increased production. In the old Nacogdoches district numerous shallow wells were drilled previous to 1895, but no very large producers were secured. A considerable amount of money has been invested in drilling wells and building a pipe line to the railroad in this locality, but operations have been of late years practically abandoned.

In the Bexar county district small quantities of heavy petroleum were produced from wells at a depth of 600 to 800 feet. This pool is located near San Antonio.

The number of wells drilled during 1902 was 252; of these 216 were productive and 36 were dry holes. The number of flowing wells was 70, and the total number of pumping wells was 782, making a total of 852 productive wells. There were 67 wells abandoned during the year. The number of tanks at the wells was 1,010, with a combined capacity of 4,917,923 barrels.

The localities in which petroleum has thus far been found are shown in the following list, arranged alphabetically by counties, the list being taken from Bulletin 18 of the University of Texas:

Anderson county, New Palestine, sand impregnation; Bastrop county, near Elgin; Bell county, western part, small quantities near Belton; Bexar county, Dulnig place, 7 miles south of San Antonio, J. Linn Survey, 10 miles south of San Antonio; Brazoria county, Kaiser mound, near Columbia; Brewster county, 6 miles east of Terlingua, in bituminous shale; Brown county, Brownwood; Burleson county, near Rita; Caldwell county, near Lockhart; Clay county, 2 miles from Hurnville, north of Henrietta; Coleman county, near Trickham; Cooke county, Muenster, west; Coryell county, Gatesville; Denton county, reported 6 miles from Denton; Duval county, Piedras Pintas, near Benavides; Edwards county, reported near Rocksprings; El Paso county, 20 miles north of Vanhorn, in small amount; Gonzales county, near Ottine; Grimes county, near Keith, Lamb Springs neighborhood; Hardin county, Saratoga, Sour Lake; Jack county, 10 miles north of Jacksboro; Jefferson county, the Beaumont field; Live Oak county, Atascosa creek, 12 miles north of Oakville; McCulloch county, near Milburn; McLennan county, near Waco; McMullen county, Crowther; Medina county, near Dunlay; Montague county, St. Jo, east; Nacogdoches county, Oil Springs, 6 miles south of Melrose, Chireno;

Navarro county, the Corsicana field, the Powell field, Frost; Nueces county, Puerto-Richard Kings' ranch; Palo Pinto county, near Strawn, 1 mile north of Mineral Wells; Pecos county, 15 miles northeast of Fort Stockton and 22 miles north of Fort Stockton; Reeves county, Pecos Valley, above and below Pecos City, 9 miles north of Toyah; San Augustine county, San Augustine; Shelby county, near Timpson; Tarrant county, near Fort Worth; Travis county, Walnut creek, 9 miles north of Austin; Wilson county, Sutherland Springs.

The total quantity of crude petroleum produced in 1902, was 18,515,017 barrels, of which 18,083,658 barrels were sold and 431,359 barrels were held in tanks by the producers.

It is estimated that at the close of 1902 storage tanks in the state contained about 7,300,000 barrels, leaving 11,215,017 barrels as the quantity which was either consumed locally or shipped from the state. The total production in 1901, excluding stocks, was 4,393,658 barrels. The gain of 1902 over 1901, excluding stocks, amounted to 311.6 per cent. The value of the crude petroleum produced in 1902 was $4,174,731, an average of 22.55 cents per barrel. Compared with 1901 the total value, excluding stocks, shows a gain of 220 per cent.

The production of crude petroleum in 1902, by districts, was as follows:

	Barrels.
Total	18,515,017
Beaumont	17,852,308
Corsicana	571,059
Powell	46,812
Sour Lake, etc. (beginning in September)	44,838

A comparative summary of the value of crude petroleum at wells sold in 1902 and 1901, by fields (excluding stocks), is as follows:

TABLE 40.—*Value of petroleum sold in Texas, by fields: 1902 and 1901.*

[Barrels of 42 gallons.]

FIELD.	1902			1901		
	Quantity.	Value.	Value per barrel.	Quantity.	Value.	Value per barrel.
Total	[1]18,083,658	$3,998,097	$0.2211	[1]4,393,658	$1,247,150	$0.284
Beaumont	17,420,949	3,563,285	0.2045	3,593,113	630,752	0.175
Corsicana	571,059	410,536	0.7189	763,424	604,249	0.7915
Powell	46,812	9,863	0.2107	37,121	12,148	0.3277
Sour Lake, etc.	44,838	14,413	0.3215			

[1] Includes small production of petroleum in Bexar county.

The following statement shows the production and stocks in the Beaumont district in 1902 and 1901:

Total production in Beaumont district: 1902 and 1901.

	Barrels.
Total production, including stocks	23,038,191
Production in 1902, including stocks	17,852,308
Production in 1901, including stocks	5,185,883

The stock in tanks at the close of 1902 and 1901 in the Beaumont fields was estimated as follows:

Stock of petroleum in tanks in the Beaumont fields at the close of 1902 and 1901.

	Barrels.
Stock in tanks on January 1, 1902	1,592,770
Increase at the close of 1902	5,707,230
Total amount in tanks at the close of 1902	7,300,000
Shipments during 1902	10,552,308
Total production	17,852,308

By the close of 1902 the iron tankage completed in Jefferson county had a capacity of 5,775,500 barrels. The capacity of the wooden tanks was 200,000 barrels. The earthen tankage is more difficult to determine, as there was a large number of earthen tanks unfinished; but it is probable that enough was completed to contain 2,300,000 barrels. This gives a total capacity of 8,275,500 barrels. There were also 50 large iron tanks, with a capacity of 2,100,000 barrels, erected by the Santa Fe Railway, the Southern Pacific Railway, and the Houston and Texas Central Railroad, scattered over north-central and western Texas, with Beaumont as a starting point. These tanks have a capacity ranging from 10,500 to 55,000 barrels, and are used for the storing of fuel oil to supply locomotives. This last-mentioned tankage, added to the iron tankage of Jefferson county, brings up the total capacity to 7,875,500 barrels for storing the petroleum produced at Spindle Top, Sour Lake, and Saratoga. There were also two large tanks erected at Sour Lake and one at Saratoga to receive the petroleum produced in the last-named localities.

The shipments of petroleum by rail from the Beaumont district are estimated as 9,646 carloads, or 1,462,968 barrels, in 1901, and 67,275 carloads, or 11,426,559 barrels, in 1902. The shipments in 1902 increased by months from 546,881 barrels in January to 1,117,624 barrels in December.

The water shipments, coastwise and foreign, in 1902 aggregated 167,390,829 gallons, of which 139,512,712 gallons, or 83.3 per cent, went to coastwise ports on the Gulf and the Atlantic, and 27,878,117 gallons, or 16.7 per cent, were exported to Habana, Cuba, and Dover and Plymouth, England, chiefly to the last-named port. Of the shipments by water only about 6 per cent were of refined petroleum. The shipments from Port Arthur aggregated 109,050,253 gallons, increasing from 5,560,044 gallons in January to 15,848,750 gallons in December, and the shipments from Sabine Pass aggregated 58,340,576 gallons, increasing from 504,000 gallons in January to 8,675,014 gallons in December. The total water shipments, 167,390,829 gallons, shows an increase from 6,064,044 gallons in January to 24,523,764 gallons in December. The cargoes were 275 in number, 144 from Port Arthur and 131 from Sabine Pass. The shipments from Port Arthur in 1901 were 8,494,794 gallons coastwise and 2,722,902 gallons to foreign ports, a total of 11,217,696 gallons. There were no shipments of refined petroleum from Sabine Pass in 1902.

The exports of crude petroleum from Port Arthur and Sabine Pass in 1901 aggregated 2,276,787 gallons, of a value of $20,061. The exports of crude and refined petroleum from these ports in 1902 to foreign countries were as follows:

Exports from Port Arthur and Sabine Pass, Texas: 1902.

	Quantity (gallons).	Value.
Total	27,878,117	$247,738
Crude	19,641,591	115,415
Naphtha	297,174	4,275
Illuminating	2,824,883	81,778
Residuum	5,114,469	46,270

Utah.—Petroleum in limited quantities has been found on the Green river in Emery county, and it is also reported near Sinbad, where a number of shallow wells have been drilled and small quantities of lubricating petroleum secured. This state in former years produced considerable quantities of natural paraffin, or black wax, from localities in the Sanpete valley, east of Salt Lake, but these have been exhausted. At the present time some gilsonite, a variety of solid hydrocarbon, is produced.

Washington.—A number of test wells were drilled in 1902 in different portions of this state in search of petroleum and natural gas. So far there have been no indications of the existence of either of these substances in paying quantities.

West Virginia.—This state produced considerable petroleum along the Burning Springs uplift a few years after the discovery of petroleum in northern Pennsylvania. It was not until about the year 1889, however, that it became of considerable importance as a producer. In the fall of that year an important well was drilled near Mannington, in Marion county, separated by many miles from any other producing territory. The development of the state after this well proved itself to be a producer was rapid. Although the great depth at which a large portion of the petroleum producing strata were found has somewhat retarded the increase of production, the most conspicuous feature in the development of West Virginia in 1902 was the opening up of the Folsom, the Pine Grove, and the Falling Timber run pools, in Wetzel county. There were also some new developments on the Big Knot and Wolf Penn run, in Ritchie county. However, no pool of any considerable size has been developed for several years, and the production of this state has been on a gradual decline since the year 1900. Some of the first wells drilled west of the Appalachian mountains were located on the Kanawha river near Charleston in search of salt brine. At this point petroleum and natural gas were found many years before oil was drilled for in Pennsylvania.

The production of petroleum in this state in 1902 was 13,513,345 barrels, which were valued at $17,040,317, an average of $1.26 per barrel. There were included in this amount 14,660 barrels of lubricating petroleum, which had a value of $2.31 per barrel. The total number of producing wells in 1902 was 11,138, and of this number 500 were flowing wells. The total number of wells drilled during the year 1902 was 2,193; of this number 1,544 were productive and 649 were unproductive or dry holes. The number of abandoned wells during the year was 1,322.

The quantity and value of crude petroleum produced in West Virginia from 1889 to 1902, inclusive, is shown in the following table:

TABLE 41.—TOTAL QUANTITY AND VALUE OF CRUDE PETROLEUM PRODUCED IN WEST VIRGINIA: 1889 TO 1902.

YEAR.	TOTAL.			REGULAR CRUDE.			LUBRICATING CRUDE.		
	Quantity (barrels).	Value.	Price per barrel.	Quantity (barrels).	Value.	Price per barrel.	Quantity (barrels).	Value.	Price per barrel.
1889	544,113	$653,827	$1.20⅛	520,511	$595,730	$1.145	23,602	$58,097	$2.46⅛

Wyoming.—The output of petroleum in this state is greatly restricted by the lack of a market near where it is produced. Large bituminous coal deposits and a thinly settled country have prevented more than a slight demand for it. There has been, however, since 1893 a regular production of superior lubricating petroleum at Salt Creek, 50 miles north of Casper, to which place it is hauled by wagons and refined. In the southwestern portion of the state, at Spring Valley, Uinta county, some petroleum of light gravity and superior quality has been produced, but not as yet in commercial quantities. There are numerous petroleum seeps in the western and central portions of Natrona county, and outcrops of sandstone largely impregnated with petroleum on the north flank of the Rattlesnake range of mountains.

In the Pope Agie district, in Fremont county, several

successful wells that flow naturally have been drilled. Some of the wells drilled in 1884 still flow petroleum when opened up. It is reported that 4,000 barrels were produced in this region and allowed to remain in earthen tanks, owing to cost of transportation, only a small portion being used for fuel and lubrication. This petroleum is quite heavy and dark and its specific gravity varies from 18° to 23° Baumé.

REVIEW BY YEARS, 1890 TO THE CLOSE OF 1901.

A summary of the principal features in the development of the petroleum industry is herewith presented; it covers the years from the publication of the Eleventh Census in 1890 to the close of 1901.

1890.—One of the most notable features in the petroleum industry in the United States in 1890 was the enormous increase in the production, a gain of 10,660,059 barrels being made over the production of 1889. The principal increase was in Pennsylvania and New York, the increase amounting to 6,970,773 barrels. Discoveries of petroleum were numerous in Pennsylvania, and the borders of some of the older districts had to be extended to embrace a wider area of productive territory. The sections conspicuous for heavy gains were the Glade Run pool in Butler county, the Shannopin pool in Beaver county, and the Montour, Wildwood, and Chartiers pools in Allegheny county. The increased production in Ohio amounted to 3,653,190 barrels and was general throughout both the Lima and the southeastern fields.

The average value of pipe line certificates in the Pennsylvania field declined from 94⅛ cents per barrel in 1889 to 86¾ cents in 1890, making a net loss of 7⅜ cents. The average price of Lima (Ohio) petroleum advanced from 15 cents per barrel in 1889 to 30 cents per barrel in 1890.

The state of Indiana was credited with a production of 63,496 barrels in 1890, as compared with 33,375 barrels in 1889, the first year in which Indiana appears in the list of productive states. West Virginia produced slightly less in 1890 than in 1889. Although the original well at Mannington was opened up in October, 1889, it required time to drill the deep wells of that region and to connect them to pipe lines, and the effect of the greater "strikes" upon the production was not at once apparent.

1891.—The amount of petroleum produced in 1891, 54,292,655 barrels, was larger than that of any preceding year and was not exceeded until 1896. The most important event that marked the year was the opening up of the remarkable McDonald petroleum field, in Allegheny and Washington counties, Pa., in July of that year. By September the production of this district reached 41,000 barrels per day. It is estimated that the total production of the McDonald field for the last six months of 1901 was over 6,000,000 barrels. This was probably the most prolific field of petroleum ever developed in the Appalachian field, when its area is considered.

The oil bearing sand was composed of beautiful quartz pebbles from the size of a pea up to that of a hickory nut. It gave up large quantities of petroleum with great rapidity. In this great reservoir the wells soon ceased to be more than ordinary producers, but a few months sufficing to measurably exhaust several of the wells which, when first opened up, flowed at the rate of 15,000 to 18,000 barrels per day. The Wildwood field, in Allegheny county, was also a factor in increasing the Pennsylvania production, although to a much less extent than the McDonald pool, and Butler county furnished some new and fairly productive wells. There was a considerable decrease in the production of the other Pennsylvania districts. There was a large decline in southeastern Ohio, owing to the low prices that prevailed. The production of southeastern Ohio in 1890 was 1,108,334 barrels, as compared with 422,883 barrels produced in 1891. On the other hand, in the Lima field there was a large increase in production.

The Appalachian field produced in the year 1891 a total of 35,848,777 barrels, which is the greatest production on record with the exception of the year 1900, when the production was slightly in excess of these figures. This large production of petroleum had the effect of reducing the price so that the average price quoted for the year 1891 was 67 cents, as compared with 76⅝ cents in 1889. In this year West Virginia began to be conspicuous as a producer of petroleum. The production of 1891 was 2,406,218 barrels, which was due to the opening up of the new field extending from Mt. Morris, near the Pennsylvania state line, to Mannington, in Marion county. Indiana also began to be conspicuous as a producer, having increased its production largely over that of 1890.

1892.—The production in 1892 showed a considerable falling off, due largely to the decline in the yield of the McDonald field in Pennsylvania. West Virginia increased over a million barrels in production, which was due to the increasing yield of the Mannington field and the newly developed Sistersville pool. The Gordon sand, underlying the Big Injun sand, was discovered to be productive south of Mannington. There was a reduction in the output of northwestern Ohio, an increase in that of southeastern Ohio, and a considerable increase in the production of Indiana, due to developments in the Trenton formation. Up to this time a greater portion of the petroleum of the Lima-Indiana fields, in Ohio and Indiana, had been sold for fuel. In this year an increasing amount was marketed for refining, owing to the process lately perfected for the removal of the sulphur. The average price received for the petroleum produced in the Appalachian field was 55⅝ cents per barrel, which, with the exception of 1861, is the lowest quotation on record. The price of Lima-Indiana petroleum was 36⅝ cents per barrel.

There was an increase in the exports of petroleum and its products.

1893.—The important features connected with the production of petroleum in 1893 were a decline in the output of the older fields, especially Pennsylvania; an increase in the amount of production in southeastern Ohio, West Virginia, and Indiana; the slight increase in price, and the increase in the refining of Lima-Indiana petroleum. There was also an increase in the quantity exported. Practically all the petroleum produced came from the Appalachian field, the Lima-Indiana field, the Florence field of Colorado, and the districts of southern California. The decline in the entire production in 1893 as compared with 1892 was 2,078,591 barrels. There was a large increase in the output of West Virginia and Indiana. The decline in the Appalachian products of 2,067,322 barrels nearly accounts for the entire shortage. The average price of certificate oil in the Appalachian field was 64 cents per barrel, an increase of 8⅝ cents over that of 1892. In the Lima field the average price of petroleum in 1893 was 47.25 cents, an increase of 10⅝ cents over that of 1892.

The increase of petroleum exports in 1893 over those of 1892 was nearly 60,000,000 gallons, and the total exportation of all varieties of petroleum amounted to 804,221,230 gallons, the largest up to that date.

1894.—The notable events in the progress of the petroleum industry in 1894 were the development of the Ormsby district, in the Bradford field in northern Pennsylvania, the opening of the Williamstown pool, in Wood county, W. Va., and the discovery of a Berea sand pool near Steubenville, Ohio. There were also some promising developments near Marietta, Ohio. The year was also notable for the advent of the state of Wyoming to the list of oil producers, 2,369 barrels being produced by this state. The quality was that of a superior lubricating petroleum. The year showed a very slight increase in production over that of 1893, but the increase in value was over $6,000,000. In the Appalachian field the combined product of New York and Pennsylvania showed a decrease of 1,294,523 barrels. West Virginia showed a slight increase over the preceding year. Southeastern Ohio showed quite an increase, amounting to 581,976 barrels. In the Lima (Ohio) district there was a decrease of only 38,960 barrels. Indiana showed an increase of 1,353,373 barrels, a gain of 58 per cent. The average price of the Appalachian petroleum in 1894 was 83⅞ cents, a gain of almost 20 cents per barrel. The average price of the Lima-Indiana petroleum was 48 cents a barrel, general average price 72 cents.

1895.—The notable features of the year were the nearly identical production of the Appalachian field with that of 1894; the increased production in Ohio, Indiana, and California; the advance of Ohio to first place, its production for the first time being greater than that of Pennsylvania; the decrease in stocks and the rise in price; and the further extension of profitable producing districts, including the opening up in West Virginia of the Elk Fork pool, east of Sistersville, and of another on Indian creek near the Big Moses well; and successful tests in southeastern Kansas. There was a slight increase in the combined production of New York and Pennsylvania and an increase of over two million barrels in the production of the Lima (Ohio) field. A slight decline, amounting to 457,499 barrels, was recorded in the production of West Virginia. There was an increase of about 700,000 barrels in Indiana and of over 500,000 barrels in California. The total production in 1895 was 52,892,276 barrels. The stocks of crude petroleum in the Appalachian field at the close of 1895 were 5,344,784 barrels, as compared with 6,499,880 barrels at the close of 1894; in the Lima-Indiana field there were 21,494,848 barrels, making a total for both fields of 26,839,632 barrels at the close of 1895.

The price for what was known as Pennsylvania certificate oil was $1.35⅛ cents, as compared with 83⅞ cents in 1894, a gain of 52 cents. In the Lima-Indiana district the average price in 1895 was 71¾ cents, as compared with 48 cents in 1894, a gain of 23¾ cents. The average price of the entire production was $1.089 per barrel in 1895.

1896.—This year was remarkable for the large increase in the production which came principally from the state of West Virginia and the Lima-Indiana district in northwestern Ohio, and from the Watsonville pool in McKean county, Pa. There was an increase in the amount of stocks held and a decrease in the price. The entire production for the year 1896 was 60,960,361 barrels, larger than that of any previous year in the history of the industry, and a gain of 8,068,085 barrels over 1895. There was a slight increase in the combined production of New York and Pennsylvania, with an increase of 4,400,000 barrels in Ohio, and an increase of 1,900,000 barrels in West Virginia. A slight increase is to be noted in the production of the state of Indiana, and a large increase in the state of Kansas as compared with that of the previous year.

The new field at Corsicana, Tex., was first opened up during 1896 and produced 1,400 barrels. The total amount of stocks held in the Appalachian and Lima-Indiana fields, at the close of the year 1896, was 33,048,492 barrels, as compared with 26,839,632 barrels at the close of 1895, a gain of 6,208,860 barrels. There was a decrease in the price of petroleum. The average value of what has been called Pennsylvania certificate oil, in the Pennsylvania field, was $1.18 as compared with $1.36 in 1895, showing a decline of 18 cents per barrel. In the Lima (Ohio) field the price fell from an average of 71¾ cents in 1895 to 66¾ cents in 1896, a decline of 5 cents per barrel. The total value of all of the petroleum marketed in 1896 was $58,518,709, an

average of about 95.9 cents per barrel. This was an increase in value of only $827,430 over the preceding year.

1897.—The total quantity of petroleum produced in the United States in 1897 was 60,475,516 barrels, a decrease as compared with 1896 of only 484,845 barrels. There was a slight increase in the production of the Appalachian field as a whole, which came principally from West Virginia. There was a decided decrease in the yield of the Lima-Indiana field in the states of Ohio and Indiana. There was also considerable decrease in the number of wells drilled in both of these states as compared with 1896. The production of petroleum in Texas amounted to 65,975 barrels, as compared with 1,450 barrels produced in 1896, and nearly all of it was produced in the Corsicana field. There was an increase in stocks and a still further decrease in price.

There was a decline in value amounting to $17,589,098. The average price per barrel for all the petroleum produced in 1897 was 67.7 cents as compared with 95.9 cents in 1896. There was a decrease of 2,450,837 barrels in the production of the Lima-Indiana field. Colorado increased its output by 23,484 barrels, and the California field by 650,634 barrels. The largest proportional gain, however, was in the Corsicana field in Texas. The stocks in the Appalachian field at the close of 1897 were 11,010,044 barrels, an increase of 1,264,322 barrels. In the Lima-Indiana field the stocks of petroleum at the close of the year 1897 were 22,762,779 barrels, a loss of 539,991 barrels. The total stocks in both fields at the close of 1897 amounted to 33,772,823 barrels, a gain of 724,331 barrels over those at the close of 1896. The average price of certificate or credit balances of Pennsylvania oil in 1897 was 78⅝ cents, as compared with $1.17⅞ in 1896, showing a decline of 39¼ cents. The average price of Lima (Ohio) petroleum was 48 cents, as compared with 66¾ cents in 1896, a decrease of 18¾ cents.

1898.—The quantity of petroleum—55,364,233 barrels—produced in 1898 showed a decrease of 5,111,283 barrels as compared with the 60,475,516 barrels produced in 1897. There was a decrease in both the Appalachian and the Lima-Indiana fields. The average price paid for Pennsylvania petroleum was 91⅛ cents per barrel, as compared with 61¾ cents per barrel for the production of the Lima-Indiana field. The initial well in Scio, Harrison county, Ohio, was completed in August. There was a large increase of production in California and Texas, but a decrease in Indiana.

There was a decrease in the number of wells drilled in the Appalachian and the Lima-Indiana fields. The total number drilled in both these fields was 7,186, of which 1,539 were dry, as compared with 8,558 drilled in 1897, of which number 1,964 were dry. The total stocks of these fields at the close of 1898 were 26,967,495 barrels, as compared with 33,772,823 barrels at the close of 1897, a decrease of 6,805,328 barrels. Stocks decreased and the price increased. The exports decreased as compared with 1897.

1899.—The entire production of the United States was 57,070,850 barrels, as compared with 55,364,233 barrels in 1898. The year was conspicuous for the increased production in southeastern Ohio, amounting to over 2,500,000 barrels, principally from the Scio pool, Harrison county, which added over 1,600,000 barrels to the output. The petroleum of this pool was found in the Berea formation at a depth of about 1,200 feet, being quite evenly distributed and of a very superior quality. There was a decrease in the production of Pennsylvania, Colorado, and Kansas, while all the other states showed an increase. There was a considerably increased production in the state of Texas. The average price of all of the petroleum produced in 1899 was $1.132, as compared with 79.8 cents in 1898, showing a gain of 33.4 cents. The average price of what is known as Pennsylvania certificate oil, which includes about 96 per cent of the Appalachian production, was $1.29⅜ per barrel in 1899, as compared with 91⅛ cents in 1898, an increase of 38¼ cents. The average price of Trenton rock, or Lima-Indiana, petroleum was 88⅝ cents in 1899, as compared with 59.4 cents in 1898, an increase of 29.2 cents per barrel.

There was a decrease in the stocks in 1899, due to shrinkage in the Lima-Indiana district, as the total stocks in the Appalachian field increased by 1,664,588 barrels. At the close of 1899 the total stocks held in the Appalachian and Lima-Indiana fields amounted to 23,997,118 barrels, as compared with 26,967,495 barrels at the close of the previous year. The decrease in 1899 was 2,970,377 barrels. The total amount of petroleum exported from the United States in 1899 was 22,643,439 barrels (951,024,441 gallons), valued at $64,982,249.

1900.—One of the important features in the development of the petroleum industry in the year 1900 is the fact that the production in that year was greater than for any previous year. The total production was 63,620,529 barrels, which amount was greater by 6,549,679 barrels than that of the year 1899. There was a large increase in the output of California, Texas, Indiana, and West Virginia. West Virginia produced 16,195,675 barrels, which was greater than the production of any previous year. There was also an increase in the number of wells drilled and in the stocks. There was an increase in the average price or value of the petroleum at the wells, the price of $1.19 being reached this year, which was the highest since 1877; the average price of Pennsylvania petroleum was $1.35¼ per barrel. The price of Lima-Indiana petroleum advanced from 89⅞ to 98¾ cents. The exports of petroleum and its products also showed a considerable gain in quantity and value.

1901.—The production in 1901 was again greater than for any previous year. It was 69,389,194 barrels, an increase of 5,768,665 barrels. There was a most

remarkable increase in the production in both Texas and California, which combined amounted to about 8,000,000 barrels. There was a decline in the product of West Virginia amounting to over 2,000,000 barrels. There were also slight declines in New York, Pennsylvania, Ohio, and Wyoming; all the remaining oil producing states showed an increase. The average price of all the petroleum produced in 1901 was 95.7 cents, as compared with $1.191 in 1900, a decrease of 23.4 cents per barrel. The average price of Pennsylvania certificate petroleum was $1.21 per barrel, as compared with $1.35¼ per barrel in 1900, showing a decline of 14¼ cents. The average price of Lima (Ohio) petroleum fell from 98¾ cents in 1900 to 86 cents in 1901. There was also a decline of 37.7 cents in the average price paid for California petroleum and a decline of 76 cents per barrel in the average price of the Texas production. There was an increase in the exports of petroleum and its products (mineral oils), which for the first time exceeded 1,000,000,000 gallons. The total value of the exports was, however, slightly less than in 1900.

On January 10, 1901, an immense gusher was drilled near Beaumont, Tex., and flowed a stream 150 feet high and 6 inches in diameter. Before it was controlled it is estimated to have produced not less than 500,000 barrels, averaging not less than 60,000 barrels per day.

The year was also notable for the organization of an immense number of stock companies in California and Texas, which secured a large amount of capital. Many of them never produced a single barrel of petroleum.

The Boulder field in Colorado was just opening up at the close of the year. It created considerable excitement, and a large amount of capital was invested in stock companies. These investments in most cases resulted in disappointment and a total loss to the investors.

REVIEW OF THE INDUSTRY IN FOREIGN COUNTRIES.

Canada.—Since the year 1862 Canada has produced a considerable quantity of petroleum. The output, however, does not supply the amount necessary for home consumption. In 1902, 11,389,390 imperial gallons of refined petroleum were produced from the crude in Canada, and 13,220,005 imperial gallons of petroleum and its products were imported. An import tax amounting to about 5 cents a gallon is imposed. For a number of years the production in Canada was over 700,000 barrels, but there has been a gradual decline in the output since 1898. The production in 1902 was 520,000 barrels. The main productive territory is situated in Lambton county, Ontario, the two principal districts being Petrolea and Oil Springs.

In quality the petroleum produced in this portion of Canada is very similar to that produced in the Lima-Indiana field, which contains a considerable proportion of sulphureted hydrogen, and it has been successfully refined in former years at Petrolea and in later years at Sarnia. There are other sections in Canada in which more or less petroleum is known to exist, but which have up to the present time yielded little or no output.

In the vicinity of Moncton, New Brunswick, several wells recently completed have produced petroleum in sufficient quantities to be successfully operated. Other localities in which petroleum is known to exist are Gaspé bay in Quebec and near Lake Ainslie in Nova Scotia, but no profitable production has been secured.

There are also indications of petroleum along the northwest coast of Newfoundland. A number of wells have been drilled and petroleum in small quantities has been found, but up to the present time no successful operations have been developed.

In the southwestern portion of Alberta a well was completed during the year 1902 which was reported to have found a considerable flow of petroleum. A well was also drilled near Calgary. There are many localities along the Athabasca river in Athabasca district where petroleum, and especially natural gas, are more or less abundant in surface indications. Although several test wells have been drilled in this section no large quantities of either have been developed.

Peru.—For a number of years this country has produced a considerable quantity of petroleum. The production for 1902 was, in round numbers, 60,000 barrels. The variety is similar to that produced in California, and is inferior in quality to the output of the eastern portion of the United States. The scarcity of good coal along the western coast of South America has added considerable interest to the development of petroleum in Peru. However, the production seems to be on the decline. Outside of the United States, Peru and Canada are the only countries on the Western continent that have produced petroleum in commercial quantities, although it is known to be widely distributed in Argentine, Brazil, Colombia, Cuba, Ecuador, Mexico, Trinidad, and Venezuela. In most of these countries there are local springs and shallow wells, worked generally in a very crude manner by the natives, which have produced a small amount of crude petroleum.

Russia.—For the first time in eight years, Russia in 1902 showed a decreased output of crude petroleum. The decrease from the output of 1901 amounted to 4,628,511 barrels, a falling off of about 5 per cent. The principal reasons for the decline seem to have been the want of organization among the producers, insufficient means of storage and transportation, and the taxes imposed by the Government upon certain territory.

A number of large spouting wells were drilled during the year, one of the largest of which was on the Rothschild plot, No. 25, at Romany, Bibi Eibat district. For a time this well yielded 80,000 barrels per day. Another large well near by produced at the rate of 100,000 barrels per day. The depth at which large spouting wells

are secured is gradually increasing, adding largely to the expense. Often several years are consumed in completing one of these very deep wells, which require many feet of casing, beginning with a size as large as 26 inches in diameter and ending with a diameter 10 to 12 inches. In some of them the wrought iron pipe and casing used weighs as much as 90 tons, which, together with the time consumed in drilling, entails a cost of from $15,000 to $20,000.

During the year a new field was discovered by the drilling of a well near Berekei station, 170 miles northwest of Baku. The Grosni field, 500 miles north of Baku, has produced considerable petroleum for the last five years. The greater portion, or 95 per cent, of the petroleum continues to be produced from an area of about 10 square miles in the Apsheron peninsula near Baku. The following table shows the yearly production of petroleum in Russia, by districts, since 1889:

TABLE 42.—*Production of crude petroleum in Russia, by districts: 1889 to 1902.*

[Barrels of 42 gallons.]

YEAR.	Total.	Balakhani.	Sabunchi.	Romani.	Bibi Eibat.	Binagadi.	Grosni.
1889	23,502,163	8,424,364	12,905,012	.....	2,172,787	.....	.....
1890	27,660,953	7,742,995	17,525,134	189,022	2,203,802	.....	.....
1891	33,565,819	9,067,861	19,992,359	1,585,342	2,920,257	.....	.....
1892	35,026,144	7,025,973	18,916,516	5,017,286	4,066,369	.....	.....

[1] "Solar and distillate" means gas oil to the United Kingdom and distillate to France.
[2] To unknown ports beyond the canal, the shipments being in bulk.

About 80 per cent of the entire petroleum production is marketed in the interior of Russia by way of the Caspian sea and the Volga river. In 1902 the quantity amounted to 2,054,990,000 gallons, of which 1,693,420,000 gallons, or over 82.4 per cent, was residuum used for fuel and 107,995,000 gallons, or 5.3 per cent, was crude petroleum. Only 12.3 per cent of the illuminating and lubricating products was marketed in the great inland portion of Russia.

The average price of crude petroleum at the wells at Baku in 1902 was 6.65 kopecks per pood, or 3.42 cents for 5 gallons, or 28⅔ cents per barrel, as compared with 8.25 kopecks per pood, or 32⅔ cents per barrel, in 1901.

WORLD'S PRODUCTION.

One of the conspicuous features of the world's production of petroleum in 1902 was the remarkable increase in the output of the inferior grades in the United States. Of the world's production the United States produced 47.9 per cent in 1902. In 1901 it produced 41.84 per cent. Another very important feature was the decline in the Russian production which, in 1902, amounted to 43.50 per cent of the world's production, as compared with 51.38 per cent in 1901.

The United States and Russia in 1902 produced 91.44 per cent of the world's production, in 1901 they produced 93.22 per cent, and in 1900 their production was 94.11 per cent.

The following table gives the production of crude petroleum in all the known countries of the world, together with the percentage for each during 1902, 1901, and 1900:

TABLE 45.—*World's production of crude petroleum: 1900 to 1902.*

[1] Does not include 508,386 barrels produced but not marketed.

There was a steady increase in the world's production of petroleum during the last three years, which would be much more marked in 1902 were it not for the fact that the Russian production showed a decrease of 4,628,511 barrels in that year. The total increase in the world's production in 1902 amounted to 11.1 per cent as compared with 1901 and to a little over 25 per cent when compared with that of 1900.

DESCRIPTIVE.

Origin.—Much speculation and controversy have been aroused among chemists and geologists as to the origin of petroleum, but no complete and satisfactory solution of the problem has yet been presented. Numerous theories have been advanced as to the original source of the carbides and hydrocarbons and their combinations, entering into the formation of petroleum, and many scientists of note have a particular theory, but there appears little possibility of reaching an agreement in the matter in the near future. Experiments in the laboratory have been made so as to combine the elements artificially and the resultant, in most instances, has been a liquid, which in appearance and composition is very similar to the natural petroleum. Petroleum has also been produced by the distillation of shales, and there are many upholders of the claim that the formation of petroleum is due to the natural distillation by internal heat of the shales and hydrocarbons found in the earth's crust. Its origin is one of the unsolved problems.

The various theories advanced by men of science to account for the formation may be in most cases narrowed down to two, each of which has found numerous supporters. These are—first, its physical origin by the distillation of organic matter in the sedimentary strata, either animal or vegetable; second, its chemical origin from inorganic matter or direct production by the decomposition of carbides through the action of steam deeply buried below all sedimentary strata.

In all of the known fields of the world the occurrence of petroleum is limited to comparatively small areas. The area of the same strata in which the petroleum is not found invariably covers a vastly greater area than the portions that are productive. This is the case also in some instances where the structural conditions may favor its accumulation, and the surrounding slates and shales are similar. When productive rocks can be traced to their outcrop there is invariably no trace of petroleum or asphaltum to be found in them. The wells drilled outside of these favored localities usually find no trace of petroleum or natural gas, although numerous sands may have been pierced which are productive elsewhere and are sufficiently open and porous to be receptacles.

Chemical and physical properties.—Petroleum, in both its liquid and solid forms, is largely made up of carbon and hydrogen. It ranges from 77° Baumé, or 0.6763 specific gravity, in the case of the lightest naphtha, condensed naturally from natural gas, up to between 1.1 and 1.3 in its more dense and solid form, such as natural asphalt, which usually contains from 50 to 80 per cent of carbon, 6 to 10 per cent of hydrocarbon,

and 8 to 10 per cent of sulphur. These solid forms are widely distributed, vary greatly in composition, and are usually associated, in varying proportions, with more or less silica and carbonate of lime.

General structural conditions influencing occurrence.—There is a vast difference in the character of petroleum produced in the United States and in foreign countries, and a great variety in the character of the strata which contains it. The infiltration of the petroleum into different sands and limestones has had much to do with imparting to it the varied physical and chemical properties. However, the structural conditions of these strata and the position they must occupy in order to bring about a concentration of the petroleum are similar in all of the productive fields. Its occurrence in small quantities in strata where the conditions necessary for concentration are wanting has in many instances been the cause of financial loss and disappointment.

Geological occurrence of petroleum and natural gas in the United States.—The intimate association of the liquid and gaseous hydrocarbons has made it difficult to separate them when one or the other is discussed. The great deposits of petroleum in the Appalachian field are in a series of sand rocks reaching up from the Lower Devonian to the Upper Barren measures or Monongahela formation, less than 100 feet above the Pittsburg coal, and embraces not less than 50 distinct horizons. The greater portion of the production, however, comes from the Catskill division, Upper Devonian, which group is petroleum bearing from northern Pennsylvania, near the northern portion of Venango county, southwest to the Little Kanawha river in West Virginia. In Warren, McKean, and Elk counties, Pa., productive sands are found below this group and are largely productive. They extend into south central New York and belong to the Middle Devonian formation. The overlying Berea and the Pocono or Big Injun and Lower Carboniferous sands are above the Catskill group in the geological scale, and are largely productive in West Virginia, southeastern Ohio, and to some extent in eastern Kentucky. The highest series of productive strata in the region east of the Mississippi river are composed of the sands of the upper and lower coal series, which are productive in southwestern Pennsylvania, West Virginia, and southeastern Ohio. The sandstone series of the Appalachian division, in 1902, produced 36 per cent of the total production.

Over 85 per cent of the petroleum produced in the United States from the beginning of production up to the close of 1902 also came from the sandstone strata of the Appalachian field. Here there are 40 distinct horizons in 3,300 feet of measures, and the individual beds of sandstone vary from 2 to 120 feet in thickness and differ in texture from an open light colored sand with layers of pebbles, which is very prolific, to sand of a close and hard texture, which it is necessary to torpedo in order to secure production. The highest productive sand of any practical value in the geological scale is the Mahoning, or Dunkard, sand of Pennsylvania or the first Cow Run sand of Ohio; the lowest is the Kane sand in Elk and McKean counties, Pa., and the sands of western New York. The Venango county sands are made up of a series of from four to six distinct beds, separated by strata of slate and shale. These sands generally contain layers or beds of white pebbles, often capped by a hard siliceous portion and separated by beds of shale and slate ranging in color from black to red. In Venango county the series has an average thickness of 300 feet from top to bottom, increasing to 430 feet at McDonald, in Allegheny county, Pa., and in portions of West Virginia. There is a general thinning out of this group toward the west and it thickens toward the east. They are generally known as the white-sand group.

Most of the sands below, and including the Speechley and Bradford sands, are darker in color and finer in texture than those above and are known as the dark-sand group. All of them consist of distinct layers, invariably capped by strata of dark slate or shale, which vary in thickness and allow the layers of sand to approach much nearer to each other in some localities than in others.

The source of the petroleum in the Lima-Indiana field is the Trenton limestone, which has produced very largely since first discovered in this field in 1885. From its first discovery to the close of 1902, this formation has produced 9 per cent of the total output of the United States. It is productive only in the region which embraces northeastern Ohio and central Indiana, known as the Lima-Indiana field. This limestone, which is usually over 500 feet in thickness, has a series of porous streaks embedded in the regular strata, and these streaks differ in composition from the great mass, being a dolomite which has replaced the carbonate of lime with crystals that are smaller than the carbonate crystal, and which do not, therefore, fill up the original space in the process of replacement. This changed and open conditions of the strata which invariably contain the petroleum (often associated with large deposits of salt water) are found at intervals of from 20 to 325 feet in extreme cases from the upper surface of the limestone.

The Trenton limestone is a remarkably regular and clearly defined deposit. The change from the Utica black slate, which caps it, to the rock is distinct and easily recognized by the driller.

The horizon in which petroleum is found in Kansas and Indian Territory corresponds to that of the salt sand group in West Virginia, located in the lower portion of the Pottsville group, resting on the Mississippian limestone, which is in a general way equivalent to the subcarboniferous limestone of southwestern Pennsylvania and West Virginia. All the remaining production west of the Mississippi river is secured from strata that are much more recent, reaching from the Permian to the Quaternary. These newer productive

measures consist of much thicker strata—a thickness of 15,000 feet is recorded in localities—and are made up of the recent sedimentary deposits. The several pools west of the Mississippi river produced 37.61 per cent of the output in 1902.

Character and composition of petroleum produced in the United States.—The Mississippi river separates the petroleum fields of the United States into two great divisions. The fields east of this line, to an almost universal extent, have developed petroleum with a paraffin base, while the fields to the west have, with a few exceptions, produced petroleum with an asphalt base. Crude petroleum with a paraffin base is generally much lighter and is much more valuable, owing to the greater quantity and superior quality of the naphthas and illuminating and lubricating derivatives it yields, as well as the paraffin, which is secured from the heavier distillates after the lighter products have been extracted.

On the other hand, petroleums with an asphalt base, in most cases, yield only a comparatively insignificant quantity of naphtha and a much smaller proportion of illuminating and lubricating products, which are of inferior quality, while the remaining distillates are principally valuable for fuel and as asphalts. The asphalt petroleums are also usually much heavier and are more difficult to transport by means of pipe lines, so generally applied in the fields producing paraffin petroleum.

These conditions restrict the market for asphalt petroleum, so that in general it is consumed as fuel oil, as distillates for enriching manufactured gas, and as asphalt. There are several exceptions to this generalization, however, as petroleum, in comparatively small amounts, is found in portions of Kansas, Texas, Indian Territory, Colorado, and California that yields refined products little inferior to the best grades of paraffin oil.

The products obtained by the refining of the Appalachian petroleum, and of oils from the other fields, are given below, in percentages, in a series of statements representing general results. There are marked differences in the composition of crude petroleum and in methods of refining. These methods are often varied, to a certain extent, to meet the demands of the market.

The following statement gives the general average products secured from the combined petroleum output of the Appalachian and the Lima-Indiana fields, which in 1902 represented 62.38 per cent of the total output of the United States:

Average products from the petroleum produced in the Appalachian and Lima-Indiana fields: 1902.

PRODUCT.	Per cent.
Total	100.0
Naphthas	13.9
Illuminating oils	58.7
Lubricants and heavy oils	8.2
Residuum (paraffin 3.42 per cent)	12.8
Loss from uncondensed light products and water	6.4

The following statement for the Appalachian field gives the average production obtained from the crude petroleum produced in western Pennsylvania, West Virginia, and southeastern Ohio:

Average products from petroleum produced in the Appalachian field: 1902.

PRODUCT.	Per cent.
Total	100.0
Naphthas	20.1
Illuminating oils	61.4
Lubricants and heavy oils	7.1
Residuum (paraffin 3.10 per cent)	6.3
Loss from uncondensed light products and water	5.1

For many years only a comparatively small proportion of the petroleum produced from the Trenton limestone, in the Lima-Indiana field, was refined. This was owing to the presence of a large amount of sulphureted hydrogen, which seemed to be thoroughly combined with the carbon and hydrocarbon which constitute the main elements of petroleum. By double refining the petroleum, however, and the oxidation of the sulphur—the black oxide of copper being used—the refiner has succeeded in producing an article which can scarcely be distinguished from the products of Pennsylvania crude petroleum, although the percentage of refined products secured is smaller.

The following is a fair average result of the distillation of crude petroleum from the Lima-Indiana field, which is located in Ohio near its northwestern extremity, reaching over into Indiana, the average specific gravity being 38.5° Baumé:

Average products from petroleum produced in the Lima-Indiana field: 1902.

PRODUCT.	Per cent.
Total	100.0
Naphthas	10.9
Illuminating oils	48.8
Metal and heavy oils	17.2
Residuum and loss	23.1

There are some refined samples which contain a small fraction of a per cent of sulphur, which does not in any way manifest itself in the process of combustion, while in others all but the faintest trace of sulphur must be removed. The original crude oil from the Lima-Indiana fields contains nearly 0.56 per cent of sulphur. The amount of sulphur found in the Pennsylvania petroleum varies from 0.025 to 0.002 per cent. Nearly all of the sulphur in the Lima-Indiana petroleum goes over when distilled, being found in both the light and heavy distillate, and it is necessary to oxidize the sulphur in order to remove it.

The gravity of naphtha varies from 90° to 60° Baumé, the lighter portions being too unstable for an accurate statement owing to their tendency to change from a liquid to a gaseous condition upon a slight rise in the

temperature or a fall in the barometer. The gravities of refined oil distillates range from 50° to 44° Baumé; that of residuum from 25° to 15°. There is usually left in the bottom of the still, after the liquid is drawn off, from 1 to 1.5 per cent of the original charge. This remains in the form of a compact cellular solid, known as "coke," which is almost pure carbon, and which is usually disposed of to parties who manufacture carbon pencils for electric arc lights. During the process of distillation the proportion of these products is varied, to meet the demand of the market, by prolonging or shortening the intervals of cutting off from one variety and beginning on the other. The lighter products are always the first to condense, then come those with an average density, and the heaviest last.

The quality of a portion of the petroleum produced in Kansas and Indian Territory in many respects resembles Pennsylvania petroleum, although the gravity is lower. Separated by intervals of dry or undeveloped territory, there are a number of productive pools, which yield petroleum of a gravity varying from 36° to 28° Baumé, although there is a considerable portion as heavy as 18° to 20°. Nearly the entire production of the lighter grades is sold to the refineries at Neodesha, where an excellent water-white illuminating petroleum is manufactured.

In these fields the lighter products amount to about 45 per cent of the total yield. A considerable portion of the heavier products is marketed as a gas enricher or as a fuel oil. The following may be taken as a fair average of the products secured from the petroleum of 36° Baumé in the Kansas field:

Average products from petroleum produced in the Kansas field: 1902.

PRODUCT.	Per cent.
Total	100.0
Naphthas	18.0
Illuminating oils	30.0
Heavy distillate	25.0
Residuum and loss	27.0

The crude petroleum found in the Florence field, Colo., is of good quality, and comes principally from the Florence pool. This pool produces a petroleum of 31° Baumé, and contains about 10 per cent naphtha and gasoline, 36 per cent illuminating oil, and 54 per cent residuum and loss.

During 1902 a remarkably pure petroleum, of 43° Baumé, was developed in a small pool, near Boulder, 30 miles north of Denver. This petroleum gave the following remarkable analysis when refined:

Analysis of petroleum developed near Boulder, Colorado: 1902.

PRODUCT.	Per cent.
Total	100.0
Naphthas	17.0
Illuminating oils	41.0
Signal oils	7.5
Lubricating and cylinder oils	32.0
Loss in refining	2.5

There are two or more different varieties of crude petroleum found in Texas. A comparatively small quantity produced in the Corsicana district is a superior oil, as the following analysis will show:

Analysis of petroleum produced in the Corsicana (Tex.) district: 1902.

PRODUCT.	Per cent.
Total	100.0
Naphthas	10.8
Kerosene (illuminating product principally)	54.5
Lubricating oils and residuum	34.7

Its specific gravity is 0.82, equal to 40° Baumé. In the year 1902 about 96 per cent of the Texas production was an inferior grade of petroleum, containing 1.4 to 1.8 per cent of sulphur, and having a specific gravity of nearly 0.92, equal to 22° Baumé. This is satisfactory as a fuel product, and a very large part of it is consumed as such. A comparatively small yield of the lighter products is secured in refining. According to Prof. C. A. Mabery, at from 145° to 200° only 4 per cent passed over as naphtha at 46° Baumé, or 0.7954 specific gravity; and at from 200° to 250° only 11 per cent passed over at 35° Baumé, equal to 0.8484 specific gravity. This latter distillate represents the illuminating product, which is much heavier than that usually secured in other parts of the United States, where it ranges usually from 0.800 to 0.815 in specific gravity.

Dr. Broverton Redwood, of London, England, records the following results in a test of a sample of illuminating petroleum refined at Port Arthur, Tex., burned in a lamp with a Hinks duplex burner; and from these results he formed the opinion that the oil represented by the sample would be found, in practical use, a thoroughly satisfactory illuminating agent:

Specific gravity at 60° F., 0.823.
Flash point (Abel test), 83° F.
Color, prime white, 2.6.
Odor, good merchantable.
Sulphur, 0.1 per cent.
Illuminating power, initial, 26.
Illuminating power, after three hours, 24.8.

Illuminating power, after six hours, 24.7.

Illuminating power, average for six hours, 25.2.

Diminution in illuminating power during six hours, 5 per cent.

Consumption of oil per hour, 1,193 grains.

Consumption of oil per candle hour, 47.4 grains.

The composition of Pennsylvania, Lima (Ohio), Beaumont (Tex.), California, and Russian crude petroleum is as follows:

Composition of American and Russian crude petroleum.

ELEMENTS.	Pennsylvania (1).	Ohio (Lima) (2).	Beaumont (3).	Beaumont (4).	California (5).	California (6).	Russia (7).
Carbon	86.10	85.00	84.60	85.03	86.93	84.00	86.60
Hydrogen	13.90	13.80	10.90	12.30	11.82	12.70	12.30
Sulphur	0.06	0.60	1.63	1.75	.....	0.40	.....
Oxygen and nitrogen	.....	.....	2.87	.....	1.25	2.90	1.10
Loss in treatment with excess of H_2SO_4	21.00	30.00	.....	39.00	.....	.....	.....

Analyses by: (1) Engler; (2) Mabery; (3) Denton; (4) Richardson and Wallace; (5) Peckham; (6) Salathe; (7) Redwood.

In some analyses the sulphur in the Beaumont petroleum is placed as high as 2 per cent. For the most part, however, it is not combined chemically, but is merely dissolved, and can, therefore, be more easily separated than that found in the Lima-Indiana petroleum.

Wyoming produced comparatively an insignificant quantity of a very high-grade lubricating petroleum, which is partially distilled and filtered under pressure before it is put upon the market.

There are a number of grades of crude petroleum produced in California, ranging from natural naphtha, with a specific gravity of 65° Baumé, to heavy black tar, with a gravity as low as 14° Baumé.

About 80 per cent is made up of the very heavy petroleum which finds a market principally as fuel. The portion that is refined does not produce such light products as the eastern oils; they are all heavier, as they have a larger proportion of carbon to that of hydrogen in their composition. Largely for the same reason, they do not have the same illuminating effect when burned in the ordinary lamp. To make them acceptable as illuminating oils they are often mixed with the eastern products.

The following analyses are of a number of varieties of petroleum produced in southern California, as determined by Prof. F. Salathe, Ph. D.:

Analysis of petroleum produced in southern California: 1902.

LOCATION.	Degrees Baumé.	Naphtha.	Illuminating distillate.	Gas distillate.	Lubricating distillate.	Asphalt and loss.
Sespe	25.20	7.30	19.50	25.00	35.80	12.40
Torry Canyon	27.00	9.20	21.50	26.00	30.30	13.00
Adams Canyon	24.00	5.20	24.60	17.30	46.00	7.00
Los Angeles	14.20	Trace.	6.00	17.50	51.50	25.00

Near Coalinga, in Fresno county, a petroleum is found in considerable quantity that is much lighter than the output of other parts of the state, its gravity ranging from 35° to 30° Baumé. Its composition is as follows:

Analysis of petroleum produced in Fresno county, California: 1902.

PRODUCT.	Per cent.
Total	100 to 100
Naphtha	16 to 20
Kerosene	47 to 48
Heavy fuel oil	13 to 10
Benzine, tar, and loss	22 to 22

The general increase in the production of the inferior grades of petroleum during the last three years, and the slight decrease in the production of the higher grades, are among the notable features in the general course of development. The very recent and large production in Texas, Louisiana, and California is one of the important facts in the growth of this industry, and indicates that in the future the refiner will be called upon to supply standard goods from inferior stock.

The calorific value of petroleum.—The calorific or heat producing properties of petroleum are measured by the pounds of water that a given weight will evaporate at a temperature of 212° F. when there is no heat lost. It has also been determined that the heating energy necessary to evaporate 1 pound of water at 212° F. would raise the temperature of 966 pounds of water 1° F. The unit used is the heat necessary to raise the temperature of 1 pound of pure water 1° F. at or near 39.1° F., which is known as the British thermal unit, generally expressed as "B. T. U." The French thermal unit, the "calorie," is that quantity of heat required to raise the temperature of 1 kilogram (2.2046 pounds) of water 1° C. The "B. T. U.," therefore, is equal to 0.252 calorie. The "pound calorie" is sometimes used by English engineers; it is the quantity of heat necessary to raise the temperature of 1 pound of pure water 1° C.; 1 pound calorie equals nine-fifths "B. T. U.," or 0.4536 calorie.

It is remarkable that petroleums of different specific gravity and chemical composition, and coming from widely separated localities and countries, have calorific values so nearly equal, as indicated by the number of pounds of water theoretically and actually evaporated per pound of petroleum consumed. In giving the test of boilers, under the head of actual pounds of water evaporated at and above 212° F., they are often credited with the results of special tests made when the boilers and the surrounding appliances were in perfect condition; therefore, in practice, the results will in many cases be lower than the figures quoted.

The specific gravity, British and French calorific equivalents, and the actual and theoretical number of pounds of water evaporated from and at 212° F. per pound of petroleum consumed are shown in the following tabular statement:

Comparative calorific value of fuel petroleum from the principal fields of the United States and from Russia.

LOCALITY.	Specific gravity (per cent).	Degrees Baumé.	British thermal unit.	French calorie.	Actual pounds of water evaporated at 212° F. in boilers.	Theoretical pounds of water evaporated at 212° F.
Pennsylvania, crude	0.8291	40	19,800	11,000	14.85	19.75
Pennsylvania, crude, heavy	0.8860	28	20,736	11,520	16.00	21.46
Ohio, Lima	0.8383	37	19,900	11,055	15.45	20.60
Texas, Beaumont	0.9210	22	19,480	10,816	14.80	20.16
Texas, Sour Lake	0.9333	20	18,950	10,535	14.40	19.62
Louisiana, Jennings	0.9090	24	19,420	10,675	14.60	20.01
California, Bakersfield	0.9589	16	19,000	10,555	14.20	19.67
Russia, Baku	0.8805	29	20,550	11,420	15.20	21.28

There is a wider variation in the fuel value of the various kinds of bituminous coal than there is in the different grades of fuel petroleum. The following tabular statement gives the water evaporated per pound of the different varieties of bituminous coal and the number of barrels of petroleum that will do the same work under boilers having modern arrangements for efficiency:

The comparative fuel value of petroleum and bituminous coal.

FUELS.	Pounds of water evaporated at 212° F. per pound of combustible.	Barrels of petroleum to equal 1 ton of coal.	Comparative cost of coal per ton on basis of petroleum at $1 per barrel.	
			Gross cost.	Less 10 per cent, owing to economy in handling petroleum.
Petroleum, 16° to 40° average	15.3	.....	.....	.....
Pittsburg, Pa., lump	10.0	4.1	$4.10	$3.69
Pittsburg, Pa., slack	7.5	3.1	3.10	2.79
Pocahontas, W. Va., lump	10.5	4.3	4.30	3.87
Cumberland, Md., lump	10.0	4.1	4.10	3.69
Ohio Hocking Valley, lump	8.0	3.3	3.30	2.97
Indiana, block, lump	9.5	3.9	3.90	3.51
Indiana, ordinary, run of mine	7.8	3.2	3.20	2.88
Kansas, average, run of mine	7.3	3.0	3.00	2.70
Indian Territory, average	7.5	3.1	3.10	2.79
British Columbia, Nanaimo	7.3	3.0	3.00	2.70
Washington, Carbon Hill	6.2	2.5	2.50	2.25

The final column gives the price per ton of coal that would be paid to equal petroleum at $1 per barrel. The poorer the quality of the coal the fewer the barrels of petroleum required to equal the heating effect.

Liquid fuel for marine purposes.—The development in the last two years in Texas, Louisiana, and California of large fields of petroleum specially adapted for fuel, with the probabilities of increased production in these localities in the near future, has added to the interest felt in the practical solution of the fuel problem. The possibility of the successful and economical use of liquid petroleum in the Southwest and West has been fully demonstrated in its application to locomotives and stationary engines, as well as to a vast number of manufactories that require a large supply of fuel.

In eastern Europe and southern Asia, along the path of the great ocean commerce and on the waters of the Black and Caspian seas, its use is increasing.

Russia and Borneo, and, to a less extent, Sumatra and Java, furnish the liquid fuel in these far-off countries. At Singapore a central supply depot of considerable magnitude has been established within the last few years. There are smaller supplies stored at Suez, Bombay, Calcutta, Hongkong, and Yokohama. There are a number of large steamers employed on the Gulf of Mexico and the Pacific coast, some of which have used liquid fuel for a number of years and have fully demonstrated its superiority. The number of petroleum burning steamers is rapidly increasing.

The utilization of the entire energy in petroleum will be accomplished only when it is mixed with the atmosphere under high pressure and exploded in the cylinder direct, in which case the costly, troublesome, and wasteful boiler will no longer be necessary.

During the year 1902 the U. S. Navy made some very interesting experiments with petroleum as a fuel, which were conducted by a special division of the Bureau of Steam Engineering known as the Liquid Fuel board, under the direction of Rear-Admiral George W. Melville, Chief Engineer U. S. Navy.

Character of lubricating petroleum in the United States.—Natural lubricating petroleum of the finest grade is often found in the higher strata of the productive series at shallow depths below the earth's surface. It is usually associated with more or less salt water, usually ranges from 32° to 34° Baumé, is not affected, so far as fluidity is concerned, by a temperature of zero or below, and commands a higher price than any other variety of natural petroleum.

The petroleum lubricants differ according to the crude petroleum from which they are made. The chemical composition of crude petroleum from different localities is not the same, showing either that the materials used in its preparation in the earth vary, or that by filtration through different strata different combinations are formed. The largest production of natural crude lubricating petroleum is from the neighborhood of Franklin, Pa., which has long been celebrated for the production of the finest natural lubricating petroleum found in the world.

There is also a large amount of lubricating oil manufactured from Pennsylvania crude petroleum, some of which is mixed with the natural product. No other lubricating petroleum is equal to that produced in the Appalachian field. Its reputation is world wide. Many railroads and steamship lines use it exclusively; the railroads using it in the United States operate 97 per cent of the total mileage. Nearly 2,000,000 barrels were exported in 1902.

Early development of petroleum in the United States.— Years ago the process of distilling natural mineral hydrocarbons was being perfected and vigorously pushed in the Eastern states, and cannel shale was imported from England and distilled at refineries near Boston and Portland. On the Allegheny river near Freeport, Armstrong county and Darlington, Beaver county, Pa.; in Ohio, West Virginia, western Kentucky, and elsewhere in this country and in Europe, there were refineries or distilling plants endeavoring to supply the demand for an efficient and cheaper lighting oil. The high price, however, prevented its universal introduction. The tallow candle was almost the universal source of artificial light before the great natural deposits of petroleum were known.

The earliest records of the travelers who first penetrated the wilderness of southwestern New York, northwestern Pennsylvania, southeastern Ohio, and south central Kentucky mention the existence of petroleum and natural gas; and the early explorers were guided to these localities by the Indians, who regarded the phenomena with religious superstition. On Oil creek, Pa., there were a number of localities where globules of petroleum and bubbles of natural gas constantly came to the surface of the water. The remains of pits that were cribbed in a crude manner were noted by the early explorers in numerous localities, extending from the mouth of Oil creek to Titusville.

From 1848 to 1856 Mr. Samuel M. Kier, of Tarentum, Pa., bottled the petroleum obtained from his salt well and sold it under the name of "Seneca oil," which name it acquired from the Seneca Indians in New York state, who were early acquainted with its medicinal virtues. The partial refining of the petroleum found in the salt-brine wells at Tarentum was accomplished by Mr. Kier about the year 1857. Owing to the rude method of refining and the poorly constructed lamps of that day there were many bitter complaints of the odor and smoke of the new illuminating oil when it was first tried.

During the years 1853 to 1860 there were four large plants erected near Freeport, Pa., on the Allegheny river, near the mouth of the Kiskiminitas river, for the distillation of a cannel slate, which in this locality varies from 2½ to 7 feet in thickness and forms the roof of the lower Freeport coal strata.

In 1856, after many failures, a plant at Freeport succeeded in producing an oil that burned with a bright light and was free from odor and smoke. Its introduction was accompanied with difficulty, owing to the dangerous and highly explosive "burning fluid" that was at that time in use. At this period there were also cannel coal distilling plants at Darlington, Beaver county, Pa., Canfield, Mahoning county, Ohio, Cannelton, W. Va., and Cloverport and Maysville, Ky. In Massachusetts parties who had formerly been engaged in the manufacture of whale oil commenced to manufacture a paraffin oil from cannel slate (called boghead mineral) imported from Scotland. About this time small quantities of petroleum were collected by Mr. J. D. Angier, on an island near the mouth of Pine creek on Oil creek, Pa., about 1½ miles below Titusville, from pits arranged one above the other, and by others who used blankets and temporary dams.

On the 30th day of December, 1854, the Pennsylvania Rock Oil Company was organized, based upon the purchase of 105 acres at the junction of Oil and Pine creeks, near Titusville, Pa., and the certificates of incorporation filed at New York city and Albany. In April, 1855, the elaborate and favorable report of Prof. B. Silliman, of Yale College, was made public, adding largely to the prospective value of the original company. The eastern capitalists hesitated to subscribe for the stock, as they were uncertain whether a company under the laws of New York could hold land in fee in Pennsylvania. To overcome this difficulty a new company, which retained the original title, increasing the capital stock to $300,000, was organized under the laws of Connecticut, September 18, 1855. A deed was executed to Ashel Pierpont and William A. Ives, of New Haven, who gave bond for the value of the property and promptly leased it for ninety-nine years to the new company.

On December 30, 1857, the property was leased to Edwin E. Boditch and Edwin L. Drake, at a royalty of 5½ cents per gallon. This lease was superseded by another to the same parties, fixing the royalty at 12 cents per gallon. Under the terms of this lease the Seneca Oil Company was formed, March 23, 1858, which drilled the first well in search of petroleum or rock oil in the underlying rocks, finding it in quantity in August, 1859, at a depth of 69½ feet. The selection of this locality was most fortunate, as nowhere else on Oil creek was petroleum found in quantity at so shallow a depth.

In the year 1860 petroleum was found all along Oil creek to its mouth; also at Henrys Bend, Tidioute, and Franklin on the Allegheny river, and at Smiths Ferry on the Ohio river.

During the year 1861 there was an immense amount of prospecting done, wherever any signs of oil were found, from central New York to Alabama, and from the Manitoulin Islands, in northwestern Ontario, to eastern Kentucky. In Europe, also, arrangements for drilling wells were completed. In Russia, Roumania, Galicia, and India, where oil springs and shallow wells or pits had produced petroleum in limited quantities for many years previously, the idea of drilling wells in order to secure larger supplies from greater depths seems only to have been entertained after the wonderful results were accomplished on Oil creek, Pennsylvania.

The year 1861 was also remarkable for the large flowing wells that were found; several are credited with flowing from 2,000 to 2,500 barrels per day. This caused a remarkable fall in the price, which was as low,

in some cases, as 10 cents per barrel, yet without purchasers. The means of storage and transportation, too, were utterly inadequate to handle such quantities. There was some oil secured from old salt wells on the Kanawha and Little Kanawha rivers during this year.

The refiners of cannel coal and cannel slate along the Allegheny river, near Freeport, and elsewhere, soon turned their attention to the refining of crude petroleum and abandoned the distillation of cannel slate. This movement materially assisted in the distribution and consumption of the new illuminant.

The remarkable growth of the industry during these early years is shown by a comparison of the yearly outputs, which are estimated as follows:

	Barrels.
1858	2,000
1860	500,000
1861	2,113,689
1862	3,056,690
1863	2,611,309
1864	2,116,109

The year 1864 showed somewhat of a decline, while the facilities for transportation, as well as the demand for the manufactured products, were steadily increasing. The price advanced in June, 1864, to $12.12 per barrel and was fairly well maintained throughout the remaining portion of the year.

In the spring of 1865 there was a freshet which did great damage to oil properties along Oil creek, in some instances, in the more exposed locations, wiping them out of existence. The productive area was considerably enlarged during the year, as oil was obtained in quantity at Church Run, Pithole, Parkers Landing, and on Dunkard creek in Greene county, in southern Pennsylvania; at White Oak and Burning Springs, in West Virginia, and at Cow Run and other localities in southeastern Ohio.

There were also numerous test wells located in eastern Kentucky and central Tennessee. The success of the original investors incited others to thoroughly canvass the country wherever a spring carried a trace of petroleum, or where natural gas was found bubbling in the water, and wherever an abandoned salt well, which had given showings of petroleum, was located, a well was projected.

The first well drilled for petroleum within the borders of West Virginia was begun in 1859 and finished in May, 1860, by the Rathbon Brothers, of Parkersburg. It was located near Burning Springs run; it was drilled by a spring pole, to a depth of 303 feet, at which point the Dunkard or Cow Run sand was penetrated and it flowed 100 barrels per day. This well and tract were sold to a company organized at Parkersburg and a second well was drilled before the close of 1860, which at 300 feet flowed 30 to 40 barrels per hour. The opening of these two promising wells was followed by a great rush of prospectors and a village was soon erected.

At the height of the development in 1863 the Confederate cavalry forces raided the region and set fire to about 300,000 barrels of petroleum that had been stored in tanks, and completely frightened away the capitalists who had invested in the field. The wells were not reopened for several years, when they were found to be unproductive.

Transportation.—In the early history of petroleum production it became necessary to find some other means of transporting the crude oil to the railroads and the navigable streams than in barrels conveyed by wagons. The measure adopted was the pipe line system, the success of which gradually displaced, in a great measure, transportation by rail and boat, and developed a new and a remarkably cheap and efficient system of transportation for both the crude and refined product. Pipe lines have proved indispensable to the general industry of petroleum and natural gas. The fact that the manufacturer could supply at a reasonable price wrought iron pipe in sizes up to eight inches in diameter which would stand 1,000 to 1,500 pounds pressure to the square inch, and had almost perfect joints, has aided greatly the economical collection and distribution of petroleum in all the producing regions.

The first petroleum from Oil creek was shipped in barrels made of oak staves banded with hoop iron. The penetrating and salient nature of crude petroleum made it difficult to manufacture barrels that would retain it, even after these barrels had been coated inside with hot glue. The difficulty of returning the barrels when empty, the uncertainty of their condition, and the liability to loss by this method of transportation, made it very unsatisfactory, and a source of annoyance to shippers and transportation companies.

About the year 1865 railroads put wooden tanks or tubs for carrying crude petroleum in each end of box cars, a car thus equipped holding from 2,000 to 4,000 gallons. While this improvement was being made by the railroads, transportation by the Allegheny river was also greatly improved by the use of bulk oil boats. These boats, each of which held from 1,500 to 2,000 barrels, were made 130 feet long, 22 feet broad, from 3½ to 4½ feet in depth and were divided into 8 watertight compartments. These were loaded at Oil City and floated down the river to the refineries at Freeport, Pittsburg, Rochester, Mingo, Wheeling, Marietta, and Parkersburg. The latter points also received crude petroleum transported in bulk boats from Burning Springs on the Little Kanawha river. When there was water enough in the Allegheny river these empty bulk boats and flats were towed upstream by steam towboats; at times of low water they were towed up by horses.

Though these improvements in transportation, both by rail and by boat, removed a part of the difficulty, there yet remained the obstacles that were experienced in moving the crude petroleum from the wells to the railroad or river. This was still done by team, and the roads were often almost impassable on account of the

depth of the mud; the method was at best expensive, and accompanied by great hardship to man and beast. It was chiefly this condition which restricted the amount of petroleum that could be put upon the market.

This condition of affairs suggested the first pipe line. The first one that was a success was constructed by Mr. Daniel Van Syckle, of Titusville, Pa., in the summer of 1865, extending from Pithole to the railroad at the Miller farm, on Oil creek, a distance of 4 miles. In the fall of the same year, Henry Harley constructed a pipe line from Benninghoff run to the Shaffer farm. The original line built by Van Syckle was purchased by the firm of Abbot & Harley, who united the two under the name of the Allegheny Transportation Company. Both of these lines were successful, much to the discomfiture of the teamsters and roustabouts, who, in some instances, interfered with the operation of the line by cutting or pulling it in two with their teams. A number of arrests followed, and from then on the pipe line was an accomplished fact and an important factor in the collection and delivery of petroleum to points where it could be loaded in tank cars or bulk boats. The growth of long pipe lines was gradual, and it was several years before it was practically demonstrated that long lines could be successfully operated. The improvement in railway transportation by the introduction of the iron tank car was a decided advance over the wooden tanks set in box and flat cars, which for a time answered all the requirements.

The tanks at the wells are connected by a system of small lines or veins which feed the main lines or arteries. These smaller lines usually are concentrated at the lowest portions of the field drained at points known as local pumping stations. A considerable proportion of the oil finds its way into the tanks at these stations by gravity and is forced to the large receiving tanks at the main station by pumps, which are often driven by natural gas engines, or it flows by gravity through suction lines to pumps into pits and is then elevated to receiving tanks. From the large receiving tanks the petroleum is forced into the main lines at a pressure often of between 600 and 900 pounds to the square inch.

These massive pumps generally represent the highest known mechanical efficiency, having triple expansion engines, Corliss valves, condensers, air pumps, and efficient boilers. They usually develop 300 to 400 horsepower and handle from 30,000 to 35,000 barrels in twenty-four hours. The boilers are economical and properly proportioned to this work, showing a duty of 16 pounds of water evaporated at and above 212° F. per pound of crude petroleum consumed as fuel. One pound of good coal will evaporate 10 pounds of water, and 1 pound of natural gas (equal to 20 cubic feet) will evaporate 20 pounds of water under the same conditions.

The main pumping plants are placed from 30 to 50 miles apart, according to the elevation of summits that must be overcome; and by the addition of a parallel line, or loop lines, for a portion of the way the distance can be increased so as to reach localities convenient for fuel or water without greater tax upon the pumps.

There are probably 4,600 miles of main trunk line, from 4 to 8 inches in diameter, in the Appalachian and the Lima-Indiana fields, reaching from northern Tennessee to Parkersburg, Cleveland, Buffalo, Franklin, Olean, and to the seaport cities of New York, Philadelphia, and Baltimore. From the Lima-Indiana field the main lines reach westward to Chicago, Montpelier, Toledo, Lima, and eastward it connects with the Appalachian system.

Kansas has an extensive system of main lines and local lines, reaching in several directions from Neodesha. In California a main line was recently completed, reaching from Bakersfield to a refinery at Point Richmond, near San Francisco, and having a branch line to Coalinga. The length of this main line is 278 miles, and it is connected near its starting point with about 150 tanks holding 35,000 barrels each. There are other smaller lines in California, extending from Pico canyon to Ventura and connecting Fullerton with Los Angeles.

Texas has in the last two years greatly increased its mileage of main line. There are four lines from 22 to 30 miles in length, reaching from the original field near Beaumont to tide water on the Gulf, and connecting it with Port Arthur and Sabine Pass. Sour Lake and Saratoga are also connected by pipe lines with Beaumont. The Corsicana field in the northeastern part of the state is connected by pipe lines with the refinery there. The length of the entire system of main lines in use in the United States in 1902 was approximately 7,800 miles, a large portion of which is double and triple lines, to which may be added 50,000 miles of smaller lines connecting the 51,774 tanks of the producing wells with the iron tanks of the receiving and transporting companies.

As early as 1875 organizations were effected and charters secured for the privilege of building pipe lines to the seaboard. However, these chartered companies at that time confined their operations to the oil regions, where they built numerous lines, usually of a 2-inch diameter, to the several railroads and their branches and to the nearby refineries. The competition among these new pipe line companies for securing the production of the fields began to be marked, especially in Butler county, Pa., and rates for delivery were cut to such an extent that the lines were in several instances operated at a loss. The demand for a consolidation of these competitive companies became more and more emphatic. Under the title of the Fairview Pipe Line a company was organized by Capt. J. J. Vandergrift and George V. Foreman, under the laws of Pennsylvania, the act bearing date of April, 1874. This company was afterwards known as the United Pipe Line Association. Into it was merged, from time to time, the other local

lines until it controlled almost the entire system. Gradually the temporary and uncertain characteristics of pipe line transportation disappeared, and more permanent structures were built.

The first trunk line, constructed in 1875, was 39 miles long and built of 4-inch pipe, now removed. It started at Carbon Center, 5 miles east of the town of Butler, Butler county, Pa., and extended to Brilliant, a suburb of Pittsburg. The trunk line to Cleveland, Ohio, was completed in the summer of 1879. This was a 5-inch line, beginning at Hilliard station, in the northern portion of Butler county, 8 miles west of Bear Creek station, and extending 103 miles to Cleveland, Ohio, where it supplied the refineries that had formerly received their crude petroleum by tank cars. There were relay stations on this line at intervals of 25 to 30 miles.

During the same year other shorter lines were laid in the Bradford field, reaching the Erie Railroad at Carrollton and Olean on the north and the Pennsylvania Railroad at Kane on the south. In the winter of 1879 and 1880 the first trunk lines to the seaboard were begun. The one in Pennsylvania, which was built of 6-inch pipe, started at Colegrove, in McKean county, and extended to Philadelphia, a distance of 235 miles; a 5-inch branch line left the main line at Millway and extended 66 miles to Baltimore, Md. The other seaboard lines started at Olean, N. Y., and were laid double; there were two 6-inch lines, running parallel through the southern counties of New York to Saddle River, N. J., where they separated, one terminating at the Bayonne refineries in New Jersey, the other passing on, under the North and East rivers, to the refineries located at Hunters Point, on Long Island. The distance between the points named was about 313 miles; the length of the pipe required by reason of loops, etc., was 762 miles. Olean was shortly afterwards connected by pipe line with Bear Creek station, on the Allegheny river, near Parker, Pa., making a continuous line to Bayonne, N. J., a distance of 420 miles.

The southern trunk line, which begins at Morgantown, W. Va., extends across nearly the whole length of the state to Philadelphia, a distance of 274 miles; it was completed in 1890.

The cheap and efficient method of transportation by trunk pipe lines, permitting the crude and refined petroleum to be delivered at seaboard at a cost much less than it was possible for it to be transported by rail or canal, marked an important era in the history of the petroleum industry. Many problems had to be solved in the construction of the first pipe line. The question of the proper selection of pipes and the making of pipe joints that would not leak under the great pressure; the manner of carrying pipe lines across large streams and rivers and over high, steep hills; the selection of proper localities for tanks and pump stations; the selection of pumps; the cleaning of the pipes when foul; and the method of equalizing distance between pump stations, by the doubling of a portion of the line, so as to equalize the work on the pumps at each station, were all new conditions and demanded the highest mechanical and engineering skill in order to overcome them. These difficulties were all surmounted in a comparatively short time.

The transportation annually of 10,000,000 tons of petroleum an average distance of 380 miles by pipe lines, with only insignificant loss by leakage, evaporation, or fire, represents a triumph of the highest engineering and mechanical skill. The introduction of the pipe line system brought about the removal of the refining branch of the petroleum industry to the centers of manufacture in the lake and seaboard cities, where at least 80 per cent of the crude product is now converted into illuminating oils and other merchantable commodities. Great numbers of the small refineries, that were formerly scattered over western New York, western Pennsylvania, West Virginia, and southeastern Ohio, have disappeared, and the business of refining oil has been transferred to the immense refining plants near New York, Philadelphia, Baltimore, Cleveland, Buffalo, and Whiting, Ind.; Port Arthur, Tex.; and Point Richmond, Cal. From these great industrial centers the manufactured petroleum finds its way to the markets of the world by ocean tank steamers, or by the bulk carriers of our inland lakes, or it is distributed by rail in tank cars to the consumers who can not be reached by these more economical methods of transportation. The important inland refineries remaining are located at Olean, N. Y.; Titusville, Oil City, Franklin, Warren, and Pittsburg, Pa.; Parkersburg, W. Va.; Lima, Ohio; Neodesha, Kans.; Corsicana, Tex., and Florence, Colorado.

The pipe line companies for many years have been the purchasers of the crude petroleum in the older fields. The pipe line company, upon application from the producer, sends an agent, generally known as a gauger, to measure and inspect the petroleum in his tank and run it into its lines. The tanks throughout the field are carefully measured and numbered, and when the oil is accepted and run into the tanks of the pipe line company a card is issued showing the number of barrels to the credit of the producer. Every tank is carefully gauged and numbered and a table prepared, which shows the number of barrels it contains for every inch of liquid from top to bottom. The temperature of the crude petroleum is also recorded and the contents of the tank examined for water. After measuring the petroleum the gauger gives the operator what is known as a "run ticket," keeping a copy for himself. The pipe line company deducts the royalty due the owner of the property according to the terms of an agreement on file at the office, and the next day the producer may secure the cash for his petroleum at the market quotation for the day or hour of his sale at the nearest home office of the company.

If the producer wishes, he can secure a certificate when his production in the tanks of the pipe line company amounts to 1,000 barrels. These pipe line certificates are made payable to bearer and are therefore transferable. They are subject to transportation charge in the district of 20 cents per barrel, and to a charge for storage at the rate of 25 cents per day per 1,000 barrels when the price is less than $1; 30 cents when over $1 and under $1.50; and 40 cents for all over $1.50 per barrel. They are to be returned for exchange to the pipe line company within six months after issue, being subject to a charge of one-twentieth of 1 per cent daily thereafter until exchanged. To cover losses by fire or lightning, certificates are subject to an assessment pro rata on all oil in custody of the pipe line. None of these charges are included in the prices as quoted and which are the prices at or near the wells. To these prices, when the oil is delivered to the refineries, charges are added for storage and transportation.

It was upon these certificates that the speculative business at the exchanges at New York, Bradford, Titusville, Oil City, and Pittsburg was based.

[1] Includes 1,520 barrels, valued at $1,370, obtained as a by-product of natural gas wells.

NATURAL GAS

NATURAL GAS.

By F. H. Oliphant.

The existence of natural gas, in greater or less quantity, accompanying petroleum, has been known since the early development of that industry, beginning with 1859. The introduction of this gas, first as a fuel and light, afterwards as a source of power, was slow. The doubt concerning the duration of the supply, the lack of appreciation of its value as a fuel, and the uncertainty as to transportation contributed largely to postpone its general use. The subsequent demonstration that it existed in large quantities in natural reservoirs, that it could be conveyed efficiently in pipe lines, and that it was of great utility as a fuel caused a remarkable increase in its consumption, and natural gas soon became one of the most valuable of mineral productions. Although used extensively as far back as 1882, it was not regarded as of sufficient commercial value to warrant statistical consideration until during the decade ending with 1890. The reports of the Eleventh Census are the first in which this industry is presented. The statistics for 1902 and 1889 are summarized in the following table:

Table 1.—*Comparative summary: 1902 and 1889.*

	1902	1889
Number of wells	15,806	[1] 2,247
Number of operators	1,967	[2]
Salaried officials, clerks, etc.:		
Number	1,923	785
Salaries	$1,810,337	$525,956
Wage-earners:		
Average number	4,678	5,899
Total wages	$2,936,279	$1,210,433
Contract work	$4,459,001	[2]
Miscellaneous expenses	$5,912,257	[3]
Cost of supplies and materials	$6,607,255	[4] $13,184,497
Value of product	$30,867,863	[5] $21,097,099

[1] Producing wells only.
[2] Not reported.
[3] Not reported separately.
[4] Includes the amounts expended for contract work, and for labor and materials used in development work.
[5] Value of fuel displaced; amount actually received by producers was $11,044,858.

The number of wells producing at the close of December, 1889, was given as 2,247, and the amount received for the gas consumed was $11,044,858. The value of the fuel displaced was computed at $21,097,099, including that displaced by gas used at oil pipe line stations, in pumping and drilling oil wells, and for other purposes. This was regarded as the actual value. The value given for 1902 is the amount received from the sale of the gas. The quantity and value of petroleum produced from natural gas wells are included in the statistics for petroleum, but the statistics pertaining to wages, employees, and other expenses are included under natural gas.

During 1902, 15,806 wells were operated; of this number, 1,250 were abandoned during the year, leaving 14,556 that were productive at the close of the year. These 14,556 wells produced natural gas valued on an average at $2,147 for each well. During the year 1889 the output of the 2,247 wells producing natural gas was valued at $4,915 per well. As a result of the severe competition in the marketing of natural gas during 1889 and the large outlay caused by the drilling of numerous wells and the construction of a number of pipe lines, the expenses were $3,876,028 greater than the amount received from the sale of the natural gas produced in that year. The quantity of natural gas marketed during 1902 is estimated to have been 205,784,453,333 cubic feet, which was sold at an average price of 15 cents per 1,000 cubic feet. The quantity marketed in 1889 is estimated to have been 552,150,000,000 cubic feet, which gives an average of 2 cents per 1,000 cubic feet. At that time a very large proportion was used for fuel purposes in mills and factories; afterwards it came to be used very generally as a domestic fuel.

A large amount was wasted and unnecessarily consumed in the years closely following the introduction of natural gas, but this waste has in a great measure been overcome in the more economical combustion of the gas, and better prices have been obtained.

The value of coal that was displaced in 1902 by natural gas is estimated to have been $39,798,833, as compared with $21,097,099 in 1889; or it may be said that while the quantity of natural gas produced in 1902 was 168.3 per cent less than that produced and sold in 1889 the revenue from it was 179.5 per cent more.

The following table shows the value of the natural gas produced in 1902, the record of wells, and the length of pipe in use up to the close of 1902, by states:

TABLE 2.—VALUE OF NATURAL GAS PRODUCED, RECORD OF WELLS, AND LENGTH OF PIPE LAID, BY STATES: 1902.

STATE.	Value of natural gas produced during 1902.	WELLS.				TOTAL LENGTH OF PIPE LAID UP TO DECEMBER 31, 1902.

[1] Includes companies distributed as follows: Colorado, 3; Missouri, 1; Tennessee, 1. Of these the company in Missouri did not report details of capitalization. The details of capitalization for the 3 companies in Colorado are included in the report on petroleum.

The capital stock and bonds issued amounted to $111,634,737. The number of shares of capital stock issued was 5,185,230, and the total par value was $92,190,870. The average value of the shares was $17.78. The dividends paid amounted to $4,944,034, or 5.4 per cent of the total par value of shares issued. The dividends paid in Pennsylvania amounted to 10.9 per cent on the stock issued, which was the largest rate returned; on the other hand, the dividends paid in Kansas amounted to only two-tenths of 1 per cent. There were 48,659 bonds issued having a par value of $19,443,867; the interest paid reached $1,041,402 and the assessments levied amounted to $1,121,776.

Employees and wages.—Wage-earners constituted 70.9 per cent of the total number of employees, and their wages were 61.9 per cent of the total salaries and wages. Table 4 shows the average number of wage-earners employed during each month.

TABLE 4.—*Average number of wage-earners employed during each month: 1902.*

January	3,821
February	3,577
March	3,633
April	3,868
May	4,113
June	4,573
July	4,633
August	5,084
September	5,670
October	5,495
November	5,332
December	6,337

The minimum average number of wage-earners employed was 3,577, during the month of February, and the maximum, 6,337, during December. The increase was great during the summer months, but was greatest toward the close of the year, when a number of large natural gas mains were constructed in West Virginia, Ohio, and Pennsylvania.

Of the total number of wage-earners employed in the United States during 1902 by natural gas companies, 94 per cent found employment in Pennsylvania, Indiana, Ohio, and West Virginia.

In the following table the number of wage-earners at each specified rate of pay is shown for the various classes of employees:

TABLE 5.—*Average number of wage-earners at specified daily rates of pay: 1902.*

4.25 and over	66	2	1	37		26

Of the wage-earners 80.2 per cent received between $1.50 and $2.49 per day. The best paid wage-earners were those classified as machinists, blacksmiths, carpenters, and other mechanics. These are intrusted with manipulation of the wells, drips, and pipe lines in the field, and have charge of the lines and regulators in the cities and towns. Although the work is not often laborious, it requires good judgment and special training to deal successfully with the various conditions that require personal attention. The employees classified under the head of "all other wage-earners" include line walkers, regulator watchmen, men who relieve the wells and drips of salt water, men who carry out instructions as to the regulation of pressure on the main lines by opening or closing the gates at the wells, and men engaged in pulling out wells and retubing them as exigencies may require.

Contract work.—Besides these wage-earners an average of 3,268 workmen were employed as rig builders, drillers, and helpers, and were paid by contractors for drilling wells. This number, added to the 4,678 wage-earners in the regular employ of the natural gas companies, increases the number of wage-earners employed in the natural gas industry to 7,946. The workmen employed by the contractors in building rigs and in drilling wells are specialists and are usually men of more than ordinary ability and bodily strength. Their wages are high, ranging from $3 to $4.50 per day; their total earnings, however, are not great because of the time lost in moving from one location to another, which occurs frequently, as a well is completed usually in from twenty to forty days.

The contractors are generally paid by the foot. The price varies greatly because of the differences in the depth of the wells and the character of the strata passed through, and the number of different sizes of casing required to complete the well, which may vary from 1,000 to 2,500 feet in depth to the gas sand.

Where only a single string of 5§-inch casing is used, the price averages about forty-five cents per foot; where two strings of casing are required, the price per foot will average 75 cents. In the deep holes in southern Pennsylvania and West Virginia, where three and in some cases four strings of casing are required to complete a deep well, the price ranges from $1.20 to $1.50 per foot. The rig, or derrick, and the casing are generally furnished by the natural gas company, the contractor supplying everything else that is necessary to complete the well, and receiving pay only in case the well is turned over to the gas company in perfect condition. The plugging or loss of a well before it is completed falls upon the contractor.

Supplies, materials, and miscellaneous expenses.—The miscellaneous expenses, which amounted to $5,912,257, were made up of rents, royalties, taxes, insurance, and sundry expenses. The cost of supplies and materials amounted to $6,607,255, and included the cost of pipe, casing, tubing, engines, boilers, pumps, drips, regulators, and sundry other items necessary for the delivery of the natural gas to the points of consumption.

Mechanical power.—The total primary power employed in 1902 aggregated 104,107 horsepower. This was used to free the gas wells of water and to compress the gas so that it could be transported in sufficient quantity to the place where the original pressure had decreased. Of this horsepower 94,595, or 90.9 per cent, was generated by steam; 7,083, or 6.8 per cent, was supplied by gas or gasoline engines; and 2,162, or 2.1 per cent, was furnished by other prime motors. The rented horsepower was two-tenths of 1 per cent of the total, the amount being 267 horsepower; of this, 225 horsepower,

or 84.3 per cent, was electric. In addition 6 electric motors, having a total capacity of 50 horsepower, were owned.

Production.—It is estimated that the United States produced over 98 per cent of the world's output of natural gas in 1902. Canada produced 1.2 per cent, and the rest of the world the remaining eight-tenths of 1 per cent. The total value of the production of natural gas in the United States for 1902 was $30,867,863. This is the largest value thus far recorded in the history of the industry, and is equal to 43.2 per cent of the value of the petroleum produced in the same year. The following table, compiled from the published reports of the United States Geological Survey, shows the production of natural gas from 1872 to 1902:

TABLE 6.—*Value of production of natural gas: 1872 to 1902.*

YEAR.	Value.	YEAR.	Value.
Total	$317,757,731	1893	$14,346,250
		1894	13,954,400
1872 to 1884	[1] 9,100,000	1895	13,006,650
1885	[2] 4,857,200	1896	13,002,512
1886	[2] 10,012,000	1897	13,826,422
1887	[2] 15,817,500	1898	15,296,813
1888	[2] 22,629,875	1899	20,074,873
1889	[2] 21,107,099	1900	23,698,674
1890	[2] 18,792,725	1901	27,066,077
1891	15,500,084	1902	30,867,863
1892	14,800,714		

[1] Estimated. [2] Value of coal and wood displaced.

If it be assumed that an average of 7 cents per 1,000 cubic feet was the price of natural gas from the time it was first introduced in 1872 until the close of 1902, the total value of the product for those years—$317,757,731—would indicate a volume of 4,539,396,159,000 cubic feet. If it were possible to confine this immense quantity of natural gas in a tank whose section was 1 square mile, and if the density would remain the same throughout, it would require a tank 30.8 miles long; or it would fill a pipe having a diameter of 67½ feet encircling the globe. This quantity represents a fuel value equal to 226,969,800 short tons of coal.

Large as this quantity of natural gas may seem, it probably does not represent more than one-half of the amount that has been taken from the original reservoirs. The early and even more recent development was accompanied by profligate waste, and large quantities were also lost during the development of the numerous petroleum fields, as many of the rocks above the petroleum strata, when pierced by the drill, were found to contain great quantities of natural gas, which was allowed to flow into the air until it was exhausted. In the early development of some of the largest fields many of the first wells, when the pressure was greatest, were permitted to discharge immense quantities into the atmosphere for months and years. Torches and escape pipes were allowed to consume and blow off great quantities. There seemed to be a general impression that these great reservoirs of natural gas were practically inexhaustible. The methods employed in applying the gas in mills and factories, and also in domestic service, were wasteful in the extreme. For many years the natural gas companies allowed their customers to consume any quantity that would pass through a certain sized orifice. The mills and factories usually paid according to the amount of finished product, using the gas as they saw fit, which was often in the most crude and extravagant manner.

In a measure this condition was brought about by a number of companies owning wells in the same field over which the declining pressure adjusted itself. When the pressure began to decline each owner made an attempt to realize the greatest revenue before the field became exhausted to such an extent that his pipes could not deliver sufficient natural gas to cause the returns to be profitable.

It has been estimated that since the beginning of the industry the greatest quantity of natural gas was consumed in 1888. This quantity, estimated to have been not less than 750,000,000,000 cubic feet, was partly utilized and partly wasted. It is estimated that it displaced fuel to the value of $22,629,875, which gives an average of 3 cents per 1,000 cubic feet.

Because of the nature, occurrence, and uses of natural gas, it is a very difficult task to ascertain the exact value and quantity consumed; every effort, however, has been made to secure these totals, and each succeeding year the records have been nearer the true amount, and the quantity unreported has gradually become less.

The following table gives the value of the natural gas produced and the value of that consumed in the United States from 1899 to 1902, by states:

TABLE 7.—VALUE OF NATURAL GAS PRODUCED AND CONSUMED, BY STATES: 1899 TO 1902.

STATE.	1902		[1] 1901		[1] 1900		[1] 1899

[1] From United States Geological Survey, "Mineral Resources of the United States."
[2] A portion of this was consumed in Chicago, Ill.
[3] Includes Indian Territory and Tennessee.

More than nine-tenths of the natural gas output of the United States was produced and consumed in Pennsylvania, Indiana, Ohio, West Virginia, and New York. The production was in excess of the consumption, as follows: $2,917,007 in West Virginia, $409,360 in Pennsylvania, $371,264 in Indiana, and $109,875 in Kentucky. On the other hand, the consumption exceeded the production by $2,430,308 in Ohio and by $1,377,198 in New York. Gas was supplied to Ohio from Pennsylvania, West Virginia, Kentucky, and Indiana. A comparatively insignificant amount from Canada was consumed in New York; the great bulk of the supply for this state came from Pennsylvania. Although gas was furnished to Ohio and New York from Pennsylvania, a large quantity of the gas consumed within Pennsylvania was brought from West Virginia. From Indiana gas was sent to Illinois as well as to Ohio.

In Indiana, Kansas, and Kentucky the value of the natural gas produced exceeded the value of the petroleum. The value of natural gas in Pennsylvania in 1902 was only $913,910 less than that of the petroleum product of the state. In this state the largest part of the total value of the output of natural gas and petroleum was obtained. The combined value of petroleum and natural gas in 1902 amounted to $102,265,602, and ranked next to coal in the list of the values of the crude mineral products of the United States.

The detailed statistics of the industry for 1902 are given in Table 8.

DESCRIPTIVE.

The principal elements in the composition of natural gas are carbon and hydrogen, which are combined, practically in the proportion of 75 per cent of carbon and 25 per cent of hydrogen forming CH_4, known as marsh gas or methane. This constitutes from 90 to 97 per cent of the different varieties of natural gas. The elements which go to make up the remainder are nitrogen, oxygen, carbonic acid, and hydrogen sulphide.

Occurrence.—In the United States the principal sources of natural gas so far developed are along the west flank of the great Appalachian uplift, extending from western New York to central Kentucky; also on the crest of the great Cincinnati uplift, extending from central Kentucky northward into northwestern Ohio and central Indiana; and in southeastern Kansas. The areas thus briefly described include the main natural gas fields which, in 1902, produced 99.5 per cent of the entire output of the United States.

Natural gas is found also in limited quantities in California, Utah, Colorado, South Dakota, Missouri, Texas, and Louisiana, and a considerable amount has been produced in these states, although the pools lack the area, volume, and force of those found in the Appalachian, Lima-Indiana, and Kansas fields.

East of the Mississippi river natural gas is found in the rock formation of the Paleozoic age, extending from the highest Carboniferous strata down to the stratum that is lower than the Trenton limestone, while in the West and Southwest the fields containing the gas are much more recent in the geological scale.

The reservoirs in which natural gas is usually found are composed of porous sandstone or limestone. In some cases a limited quantity of the gas has been found in shales, but this gas may be regarded as having gradually accumulated from the underlying rock formation. Almost invariably the large reservoirs have been developed in the strata on or near the crests of the anticlinal or rock waves, while petroleum has been generally collected on the lower horizon; and frequently salt water is found at a still lower level. Sometimes, however, the gas fields are entirely isolated from the petroleum producing areas. There are three leading requisites necessary for the accumulation of natural gas in merchantable quantity. These are as follows:

First. An open or porous strata capable of storing the gas under pressure.

Second. A slate or shale covering of this porous

strata to seal in the upper surface and the fractures of the strata saturated with natural gas.

Third. A sufficient flexure or relief of the strata to enable the separation of the salt water and the petroleum from the natural gas.

In order that the production of the gas may be profitable, the reservoirs must be packed with high pressure gas over a large area.

The original rock pressure has been found in very many instances to equal the hydrostatic weight of a column of water of a height equal to the distance from the point where the reservoir is pierced, to the surface. If it takes 2.3 feet of head of water to equal 1 pound to the square inch, or 43 pounds to the hundred feet, then a depth of 1,000 feet will equal 430 pounds to the square inch. This proportion of the depth to the pressure has been proven to be quite near the actual results obtained.

The rock pressure and the output of gas wells are usually measured when the well is new and they are at their maximum. Even the longest life of a gas well is short, and the rock pressure decreases with every foot of natural gas taken out. It is not usual for wells having the greatest rock pressure to produce the greatest volume of natural gas, as an open pebble sand gives up its stored products more rapidly than a sand of closer texture; therefore the more open the texture of the strata, the shorter but more vigorous will probably be the life of the pool. Many pools that were most vigorous are almost entirely destitute of natural gas to-day. The gas in some of them has been so far removed by gas pumps that when they are opened the air flows into the vacuum in the porous strata once packed with high pressure gas. In many virgin fields, especially in the beds of streams, innumerable small vents and bleeders are often found, from which there is an escape of more or less natural gas in the form of bubbles. Against the hydrostatic pressure the bubbles find vent, and escape into the air. As the pressure decreases, the water usually climbs up toward the more elevated portion of the reservoir. These innumerable vents, during the ages that have passed, have acted as safety valves, and have allowed the escape of many millions of cubic feet of gas into the atmosphere. The contents of the known reservoirs are probably but a small fraction of the gas that has been dissipated in the air.

The search for and the production of petroleum, moreover, has caused a great loss of natural gas, since frequently the gas is found in the higher portion of the sand containing the petroleum, and is tapped before the petroleum is reached. In many cases the natural gas has been allowed to flow into the atmosphere and be wasted until the pressure was sufficiently exhausted to permit drilling to proceed.

In the most important fields of Pennsylvania, the original rock pressure varied from 375 to 1,000 pounds to the square inch, the average being about 700 pounds. The output of some of the largest wells in the state ranged from 7,500,000 to 25,000,000 cubic feet in twenty-four hours. A well producing about 1,000,000 cubic feet is considered a good well.

Some of the original wells in the Trenton field in Ohio gave large outputs when first opened. In the vicinity of Findlay and Bairdstown several very large wells were developed during the early history of the field, when the original rock pressure was about 450 pounds to the square inch, and several wells near the location named produced from 5,000,000 to 17,000,000 cubic feet in twenty-four hours. Now there is an average of less than 20 pounds of pressure.

The more recently developed field in Knox county near Mt. Vernon, Ohio, contains a number of wells with an output of from 5,000,000 to 9,000,000 cubic feet in twenty-four hours, the original rock pressure being about 680 pounds to the square inch. The gas in this field is found in the Clinton limestone, at a depth of about 1,850 feet.

Nearly all the natural gas produced in Indiana comes from the Trenton limestone. The wells at first were generally large producers, the output ranging from 1,000,000 to 10,000,000 cubic feet in twenty-four hours. The original rock pressure was 325 pounds to the square inch; it is now less than 70 pounds, and even this light pressure is being rapidly diminished. There are localities where the original pressure is exhausted.

In West Virginia there are a number of powerful gas wells, the productive sands of which are deeply buried. The Big Moses well, on Indian creek, Tyler county, was in its day one of the very largest wells known, and for a few years delivered immense quantities of gas. The estimated output of this well when first opened was 35,000,000 cubic feet per day. Its life was only about two years, the nearness of petroleum deposits, which were soon after developed, allowing the escape of gas and a great decline in pressure soon followed. There are numerous deep wells in West Virginia that have a rock pressure of over 1,000 pounds to the square inch; in some instances 1,500 pounds is recorded. A number of deposits of natural gas have been found in three or more distinct sands or horizons; the deepest wells measure about 3,200 feet. During the year 1900 a very large natural gas well was drilled near Goodhope, in the southern part of Harrison county. This originally had an output of 45,000,000 cubic feet per day. There are numerous wells in this section, and in the western portion of Marion and Monongalia counties there are many with a capacity of from 1,000,000 to 15,000,000 cubic feet. Wetzel county also contains powerful gas wells with a depth of from 2,700 to 3,100 feet.

Southeastern Kansas has developed very fair natural gas wells of good endurance, the rock pressure of which is from 280 to 335 pounds to the square inch.

Many of them have a volume of over 7,000,000 cubic feet per day, the depth being about 900 feet.

Historical.—The existence of natural gas was discovered through the observation of bubbles in springs and streams, many of which would sustain a flame for an indefinite period. These springs and natural vents were known to the early pioneers, while for centuries before they had been known to the Indians, who viewed them with a certain amount of awe and veneration, since they cast a weird light at night upon their camping grounds.

The white men drilling wells for salt brine were in many instances surprised by the outburst of imprisoned natural gas when their crude drills penetrated the sealed-in reservoirs. These outbursts were often of sufficient violence to blow out the drilling tools, and in some instances they ignited and destroyed the primitive drilling plant.

In subsequent years the search for petroleum developed many pools of natural gas of high pressure, and in the early development of petroleum the finding of this gas was considered a dangerous and unwelcome discovery, although it was known and utilized in a few localities long before the first well was drilled for petroleum in 1859.

Natural gas has been developed almost entirely in the northeastern portion of the United States, there being only a few wells, comparatively, in the west and southwest portions. In Canada some has been found, a part of which has been consumed in the United States. Although natural gas is distributed largely over the entire globe, its development and use outside of the United States and Canada has been insignificant. There is at present a small consumption of natural gas in England, in Sussex county. Holland makes use of it for the partial illumination of two small villages on the Zuyder Zee. Galicia, Roumania, Russia, India, Persia, and Japan use it in a limited way in the operation of petroleum wells and in refineries.

One of the most noted natural gas vents or springs located by the pioneers was on the northern bank of the Kanawha river, in West Virginia; this spring was visited in 1776 by General Washington, who was greatly impressed by the phenomenon. There was also a well-known gas spring on the Big Sandy river 50 miles above its mouth; and numerous springs were known to exist on what has been called the St. Marys uplift, which extends 25 miles north from Burning Springs on the Little Kanawha river. In the early history wells drilled for salt water in the area extending from the Cumberland river, Ky., to above the mouth of the Kiskiminitas on the Allegheny river, very often developed large flows of natural gas. In some cases the flow of these wells was persistent, in other cases it was soon exhausted.

The earliest economic use of natural gas in this country was, in all probability, in 1821, when it was used in the lighting of the village of Fredonia, Chautauqua county, N. Y. On the banks of the Canadaway creek, on which Fredonia is situated, a well 1½ inches in diameter was drilled to a depth of 27 feet, and from this was obtained a flow of natural gas sufficient for 30 burners, the light of each of which was considered to be equal to that of two good candles. Several years later, in 1825, a small gasometer was introduced, and afterwards a number of shallow wells were drilled, and from these more or less natural gas was secured. In 1871 a well developed a very large flow of natural gas when at the depth of 1,200 feet it pierced the Corniferous limestone.

A well dug for water at Findlay, Ohio, in 1838 produced large quantities of natural gas near the crest of the great Cincinnati uplift. The gas was collected and conveyed into the house of Mr. Daniel Foster, where it was utilized for nearly fifty years, until the regular development of the great Findlay gas field began in November, 1884.

In 1841 natural gas was developed in association with salt brine in a well drilled on the Kanawha river in West Virginia, near where an original gas spring was located. The pressure was sufficient to force the salt brine up into a large hogshead where the salt and gas were separated. The salt brine was diverted into salt pans and the gas conducted to the furnaces underneath, where it was successfully used as fuel for the evaporation of the salt water.

More or less gas was developed on Oil creek, Pa., and in the surrounding section, by the wells drilled in the search for petroleum in the winter of 1859 and 1860. Some of these wells produced gas only, and others produced both gas and petroleum. For several years it was the common practice to conduct the gas to a safe distance and there consume it to get it out of the way. The high price of coal and wood and the extremely poor roads, finally induced some of the more venturesome to try to burn it under boilers. This experiment was so great a success that natural gas became a most efficient substitute for coal and wood. In its early application, however, numerous fires and explosions were caused by overpressure, because at that time no automatic method of regulating the pressure was known.

One of the first applications of natural gas for fuel purposes was in the year 1868, when a manufacturing company in Erie, Pa., drilled a well 600 feet deep into the Devonian shale. This well produced a considerable amount of gas when first opened, but the output gradually declined. Many wells that were sufficiently large to supply one or two dwellings were afterwards drilled in this locality.

Near Titusville, Pa., in 1872, thirteen years after the drilling of the first oil well, a powerful natural gas well was drilled on the Newton farm, 5½ miles north of the town. The gas from this well was conveyed into the town by a 2-inch gas main, which furnished 250

consumers with light and fuel. Afterwards the original line was reinforced by a second one 3¼ inches in diameter. The two lines maintained a steady pressure and a satisfactory supply. This was the first natural gas plant which supplied light and heat in any large and permanent quantity by methods and appliances similar to those in use to-day. It is looked upon as the beginning of the industry which has since assumed such large proportions.

During the year 1873 natural gas was successfully introduced for fuel and light at numerous localities in Venango, Butler, and Armstrong counties. It was also introduced at Leechburg, in Armstrong county, in the same year, the supply being obtained from an abandoned well drilled for oil in 1871, and was successfully applied in heating and puddling furnaces.

Iron mills at Etna, near Pittsburg, Pa., were the first large mills to be supplied by a gas line of any considerable length. The supply was used for years. This line was built in 1875, and extended from the iron mills to the Harvey well, near Lardens mills in Butler county, a distance of 17 miles. This well was one of the largest known at that time.

By the close of 1883 several pipe lines were supplying the manufacturing establishments and the domestic service in Pittsburg, Pa., the supply being from the Murrysville pool, in Westmoreland county, which had been developed several years previously. In 1885 the Grapeville and the Speechley pools were first developed. The increase in its use was remarkable, and a number of pools in Washington, Butler, and Beaver counties were opened up and connected by pipe lines. In 1886 the gas field at Findlay, Ohio, began to be prominent. Afterwards a large field in Indiana was developed. The development of these large reservoirs of natural gas, hitherto unknown, seemed to impress the general public and many of the operators of natural gas fields with the idea that these reservoirs were practically inexhaustible. The fact that the quantity of gas withdrawn from any of the large fields by one or two wells decreases the volume and pressure very slowly caused a false impression as to the extent of the reservoirs. As the fields were developed, however, and many wells reached the gas reservoirs, the decline in the pressure became more rapid and noticeable.

In Pennsylvania, Ohio, and Indiana immense quantities of gas were consumed in wasteful and extravagant display, which in numerous instances almost turned night into day. This extravagance was not realized until the fields began to be seriously depleted. In the mills and factories the application of gas as a fuel was made in a wasteful and unscientific manner; at least double the quantity of gas necessary to do a given amount of work was consumed.

In 1890 and 1891 many reforms tending to improve methods of storing, transporting, and consuming natural gas were inaugurated. The meter was introduced, which at once made it to the interest of the consumer to see that consumption was economical. The wells were controlled from the head office by telephones, so that when the supply was more than enough the gates at the wells were shut. The wells were watched more vigilantly, salt water was kept out with more care, and leaks and joints and all pipe connections were carefully examined and repaired. The use of large pipes by many of the gas companies began about this time, enabling them to send larger quantities to points of consumption at reduced pressure.

Uses.—Natural gas is used principally as a source of light and heat in domestic service. It is employed extensively in industrial establishments for many purposes, notably in the manufacture of glass, in the generation of steam, puddling of iron, in roasting ores, in heating furnaces, and in the manufacture of steel, and it is also utilized as a source of power in the gas engine, in drilling and operating oil and gas wells, and in pumping oil. The heat value stored in natural gas is greater than that caused by any artificial combination of carbon and hydrogen, and is a perfect fuel as it issues from its original rock-sealed reservoirs. No preparation is necessary for its combustion and no residue is left. It is not affected by ordinary temperature and it is easily distributed by pipes to points of consumption. It is a most economical source of light and power, and an ideal household fuel.

The illuminating properties of natural gas vary in different localities, because of the difference in the percentage of the heavier hydrocarbon, ethane (C_2H_6). All the natural gas found adjacent to petroleum fields has a larger proportion of ethane than the gas farther removed, and therefore the candlepower is considerably greater. Ordinary natural gas, if consumed with a common tip at the rate of 7 or 8 cubic feet per hour, will yield about 6 or 7 candlepower. In an ordinary Argand burner with chimney, it will give about 12 candlepower in consuming 5 to 6 cubic feet per hour. When natural gas is consumed in contact with a mantle of alkaline earth (thoria, etc.), the result is the cheapest and best illuminant known. When the price of natural gas is 25 cents per 1,000 cubic feet, and 50 candlepower is obtained from a consumption of 2½ cubic feet per hour, the cost per candlepower per hour is only 0.00125 of a cent.

There were 510,000 domestic consumers of natural gas during 1902, and it is estimated that in the western portions of New York and Pennsylvania, in central and western West Virginia, and in Ohio, Indiana, and Kansas, not less than 4,500,000 persons received the benefit of natural gas used as a fuel and an illuminant. Over 8,000 manufacturing establishments were also supplied.

The introduction of natural gas into the household, for which it is eminently fitted, has been accomplished without personal inconvenience or loss of life, except in very rare cases. The risk from fire is less than when wood and coal are used. There have been some cases of asphyxiation when a stove has been burned in a room without a flue connection, as it has been found by

experiment that combustion under these conditions is imperfect, especially so if the air in the room becomes more or less saturated with carbonic acid and the vapors of water, the result being the formation of poisonous carbonic oxide.

The calorific value of natural gas varies slightly in different localities, as the amounts of carbon and hydrogen vary. Those natural gases which contain the highest percentage of carbon give the best results in evaporating water. The standard used in measuring the evaporation of water is called the British Thermal Unit, written B. T. U., and is the amount of heat necessary to raise 1 pound of pure water 1° F. at or near 39°, which is the temperature of the maximum density of water. The quantity of air necessary for the perfect combustion of natural gas varies from 10.4 to 10.8 parts of air to 1 part of natural gas. The products of combustion are water and carbonic acid.

The ultimate heat units in any fuel are not all available for the conversion of water into steam, a proportion being lost by radiation and in causing sufficient draft to supply the fresh air that is required to keep up the combustion. A number of tests have fully demonstrated that when ordinary care is taken in burning natural gas under boilers in actual service, 1 cubic foot of natural gas will do the work equivalent to the evaporation of 1 pound of water at and above 212° F. Since 20 cubic feet of ordinary natural gas weigh 1 pound, 1 pound of natural gas will evaporate 20 pounds of water, while, under similar conditions, 1 pound of petroleum will evaporate only 16 pounds of water, and 1 pound of good coal will evaporate but 10 pounds of water; therefore 10 cubic feet of gas is equal to 1 pound of coal, or 20,000 cubic feet will equal 1 ton of coal.

Only two articles have been made directly from natural gas; they are lampblack and gas coke. Lampblack is still made, but gas coke ceased to become a product when natural gas as a fuel was consumed in an economical manner. In isolated districts, where it is difficult to convey the natural gas to market, numerous wells have been made profitable by the conversion of the gas into lampblack. The process is extremely wasteful, as the amount of carbon actually secured is probably not more than one-twentieth of the carbon contained in the gas consumed. In the manufacture of lampblack or carbon black a great number of small jets are made to impinge upon a pipe, through which there is a circulation of water to keep it cold. The carbon is deposited on the pipes in very thin films and accumulates very slowly. Automatic scrapers and brushes are arranged to collect the deposit, so that the flames can have the clean, cold surface of the pipes upon which to deposit a fresh supply. The lampblack thus secured is said to be the very finest, and is used extensively at home and abroad.

Gas coke is a product of the imperfect combustion of natural gas when the unconsumed portion is highly heated. Under such condition the gas is decomposed and pure carbon is deposited. Generally the deposit was obtained from the fire boxes of the heating furnaces used in the manufacture of wrought iron, and found a ready sale for use in the manufacture of electric light carbons. It is similar in appearance to the coke formed from coal, and has a metallic ring when struck with a hammer.

The measurement of the output of gas wells.—To ascertain the outflow of a gas well in cubic feet per hour it is necessary to determine the momentum, either by the application of the Pitot tube or, if the pressure is greater than 5 pounds, by the use of an accurate steam gauge. In using the Pitot tube one end of a shoot pipe is placed at right angles to the flow from the well and as nearly even with the orifice of the pipe as possible—one-third of the diameter from the outer edge. Leading away from this small nipple there is an elbow and a piece of pipe attached to a siphon gauge, in which the gas presses against the water or mercury. There is also a scale attached to the gauge showing the inches and tenths of an inch of the height of the column caused by the momentum. This method of application and the formula for determining the flow were first applied by Prof. S. W. Robinson, of the Ohio State University.

Compressors.—The pressure in most of the original fields at first was ample to convey large quantities of gas a number of miles through medium sized pipes. In after years a gradual reduction in the pressure made it necessary to install powerful compressing machinery. At first gas was used in the generation of steam as a motive power; afterwards the most successful and economical compressors were those in which gas was exploded directly in the cylinder.

Many of these compressor plants installed by the natural gas companies are models of the highest mechanical efficiency, some of the individual compressors developing as much as 2,000 horsepower and weighing from 250 to 500 tons. The more recent ones are so constructed as to use natural gas engines instead of steam engines for motive power. By the operation of compressors with the gas engine there is a saving of from 40 to 50 per cent in the amount of gas used, as compared with that consumed under boilers supplying double expansion engines. One of the first gas compressor plants using natural gas as a motive power is in use at Halsey, McKean county, Pa. This plant consists of four horizontal gas cylinders, in which natural gas is exploded, each having a diameter of 25 inches and a stroke of 4 feet. These cylinders are set tandem, two on each side of the main shaft, which carries two 13-foot fly wheels and operates four compressor cylinders. Two of these cylinders are high-stage compressors and two are low-stage compressors, the former being 15 inches in diameter and the latter 31 inches in diameter; the stroke is 2 feet. The main dimensions are: Length, 75 feet, and breadth at fly wheel, 18 feet. In this engine one horsepower per hour is produced by the consumption of 9 cubic feet of natural gas.

The natural gas engine.—Since the first successful

use of the natural gas engine about ten years ago, its application has been rapid as well as eminently successful; wherever natural gas could be secured this engine has been installed, and has fully demonstrated its economy and reliability. One of its greatest triumphs is that it dispenses with the costly and extravagant boiler.

Its merits are fully demonstrated in its application to the pumping of petroleum wells and the operation of the smaller force pumps used in the transportation of the petroleum. Its general introduction into the petroleum producing fields has enabled the operator to pump economically small wells that otherwise could not be operated, and it has also enabled him to handle large quantities of water where petroleum must be secured at a small outlay. Petroleum wells are often pumped in clusters of from 5 to 25, the number varying according to the depth and other conditions. Where the wells are comparatively shallow, and not too far apart, they can be pumped readily and with small loss by means of rods operated by steam or gas engines. Formerly deep wells were operated by a single boiler in or near the center of a cluster of from 4 to 6 wells, each of which had a steam engine connected with steam pipes radiating from this boiler. The loss by condensation when this method was used was very great.

The gas engine has in many instances replaced the steam engine, the change often being effected by the removal of the steam cylinder and the substitution of a gas cylinder. The boiler is dispensed with. The gas engine will run unattended for hours, as it is only necessary that it be kept lubricated. The steam engines usually employed in petroleum operations are generally not well cared for, so that the steam used for the work accomplished is often extravagant. In ordinary practice the internal combustion engine, of which the natural-gas engine is a type, is most economical, and equals in effectiveness the triple expansion condensing engine. When the natural gas engine is operated in the most economical manner, there is a saving of nearly 50 per cent in fuel over that required to be consumed under boilers to operate high duty steam engines, and a saving of about 90 per cent over the consumption required for the ordinary steam engine.

Distribution of natural gas to the consumer.—Almost the entire production of natural gas is distributed to the consumers by wrought iron pipes, which vary from 1 inch to 20 inches in diameter. There are also in use a number of miles of riveted wrought iron pipes of a diameter of 3 feet. Lately many long lines have been constructed of pipe 18 and 20 inches in diameter. The pressure at the field end of these lines is in some instances as high as 400 pounds to the square inch, but it is usually from 100 to 200 pounds. Where the natural well pressure is not sufficient, it is increased by large compressors, before described.

Wrought iron pipes 6 inches and less in diameter are usually connected by collars with threaded joints. Recently the joints for the larger diameters have been made of sleeves of a larger diameter, between which and the pipe rubber packing is forced by flanges drawn together by bolts. This variety of joint is satisfactory in every way, and has a number of advantages over the screw couplings for larger diameters. It overcomes the trouble due to the expansion and contraction of the pipe line without a resort to fine bends; it enables the pipe to swing more or less; it adjusts itself to the inequalities of the surface; it cheapens the first cost, because no threads have to be cut; it is not so easily injured in transportation, and it is efficient in preventing disintegration by electrolysis in localities where electric roads are operated. Usually the main line pressure is reduced near the city or town line to a pressure of from 20 to 50 pounds, and the gas is fed into an intermediate system of pipes supplying the regulators that deliver the natural gas into the mains from which the consumers are supplied.

In the cities and towns there are two methods of distribution. The more common system is called the low pressure system, and usually carries a pressure of from 3½ to 7 ounces to the square inch. This system consists of a series of pipes from 2 to 12 inches in diameter laid in the street at a depth of from 2½ to 3 feet, the largest sizes being placed in the localities of the greatest consumption. To these pipes are connected the service pipes, which are usually from 1 to 1½ inches in diameter, and lead into the consumers' houses. Between the high pressure lines and the low, automatic regulators are placed, adjusted by weights and diaphragms, in such a manner that the pressure remains almost constant, even when more or less natural gas is conveyed from the high to the low pressure. A series of liquid seals are used in connection with most of the regulators, which prevent any pressure over 16 ounces on the low side from getting into the dwellings; the liquid seals will blow out when such pressure is reached.

Another system is that of placing a reducing valve inside or near each house, this valve being connected with a smaller pipe conveying a higher pressure which is reduced by an individual regulator to a pressure of from 4 to 6 ounces. The points of consumption are in many instances from 100 to 250 miles distant from the place of production.

The total length of pipes of all sizes from 2 inches up to 36 inches in diameter in use in the United States for conveying natural gas at the close of 1902 was 131,859,636 feet. This is equal to 24,973.41 miles—enough to more than girdle the earth at the equator.

Natural gas is usually sold to the consumer by the cubic foot, at a standard pressure of 4 ounces to the square inch, or 36 pounds to the square foot, at a temperature of 60° F. In many instances it is convenient to dispose of the gas to consumers at higher pressures, and then it is necessary to construct meters of proportional strength. The mean pressure of the atmosphere for the elevation at which most of the natural gas is sold is assumed to be 14.4 pounds to the square inch.

TABLE 8.—DETAILED

		United States.	California.	Illinois.	Indiana.
1	Number of wells	15,806	29	28	6,861
2	Number of operators	1,967	15	23	880

STONE

STONE.

By George P. Merrill, Ph. D.

As early as the Seventh Census, statistics of the production of stone for building and decoration were shown. Under the name of "stone and marble quarries" a total of 1,144 quarries, with an output valued at $8,180,115, was reported. This, however, did not include the value of stone burned into lime, which was separately reported and amounted to $2,286,242. There were also 5 slate quarries, with a product valued at $29,056. Statistics for slate and marble quarries have been shown at each subsequent census, but the first systematic and fairly satisfactory report of the stone industry, as a whole, was begun under the direction of Dr. George W. Hawes at the time of the Tenth Census in 1880. The unfortunate death of Doctor Hawes, in the midst of his labors, prevented the carrying out of his plans as completely as might have been desired, but enough was accomplished to establish a basis for future work and furnish material for comparison.

It will be noted that since 1880 the increase in number of quarries was 4,239, and in value of products, $52,086,383. The industry has, therefore, practically quadrupled during the twenty-two years. No comparison can be made between the wages for 1880 and those for 1902, as wages were not reported in 1880; the increase in salaries and wages from 1889 to 1902, however, was $11,448,369, or 37.5 per cent.

The following table presents comparative statistics for all classes of stone for 1902, 1889, and 1880:

Table 1.—*Comparative summary: 1880 to 1902.*

	1902	1889[1]	1880[1]
Number of quarries	5,764	4,163	1,525
Number of operators	5,470	[2]	[2]
Salaried officials, clerks, etc.:			
Number	5,279	[3] 1,086	[2]
Salaries	$4,488,339	[4]	[2]
Wage-earners:			
Average number	71,156	[3] 51,288	[5] 39,723
Wages	$37,515,907	[4] $30,555,877	[2]
Miscellaneous expenses	$3,976,865	$2,293,706	[2]
Cost of supplies and materials	$10,739,736	$7,923,220	[6] $192,175
Value of product	[7] $70,462,438	[8] $53,035,620	$18,376,055

[1] Exclusive of silica sand.
[2] Not reported.
[3] Foremen included as wage-earners.
[4] Salaries included in wages.
[5] Greatest number employed.
[6] Value of explosives.
[7] The United States Geological Survey reports under "glass sand" (this is not included in stone) 943,135 short tons, valued at $807,797, which includes glass sand obtained from banks. Census figures for "silica sand," included in stone, are $421,289 for the value of the product, and embrace only the sand produced at sandstone quarries by crushing the rock. The production of stone reported by the Survey does not include limestone, valued at $210,798, consumed in the manufacture of cement.
[8] Includes bluestone, purchased by wholesale dealers, valued at $939,694.

Capital stock of incorporated companies.—Of the 5,470 operators of stone quarries, 754 were incorporated companies. Details of capitalization were reported by 675 of these, and are shown, by classes of stone, in the following table:

Table 2.—CAPITALIZATION OF INCORPORATED COMPANIES: 1902.

	Total.	Limestones and dolomites.	Marble.	Sandstones and quartzites.	Silica sand.	Siliceous crystalline rocks.	Slate.

Capital stock and funded debt amounting to $103,347,650 was reported for all classes of stone, of which $35,509,735, or 34.4 per cent, was invested in quarries of limestones and dolomites; $20,318,400, or 19.7 per cent, in marble quarries; $19,380,825, or 18.7 per cent, in quarries of siliceous crystalline rocks; $16,219,850, or 15.7 per cent, in quarries of sandstones and quartzites; $11,323,565, or 11 per cent, in slate quarries; and $595,275, or five-tenths of 1 per cent, in quarries of silica sand.

The following table shows the number of operators, grouped by value of product, with the percentages the number and value are of the totals:

TABLE 3.—*Operators by value of product: 1902.*

PRODUCT PER OPERATOR.	OPERATORS.		VALUE OF PRODUCT.[1]	
	Number.	Per cent of total.	Amount.	Per cent of total
Total	5,470	100.0	$71,204,313	100.0
Less than $500	1,789	32.7	322,752	0.4
$500 but less than $1,000	498	9.1	357,244	0.5
$1,000 but less than $10,000	1,868	34.2	7,386,264	10.4
$10,000 but less than $50,000	1,004	18.3	22,580,841	31.7
$50,000 but less than $100,000	188	3.4	13,612,105	19.1
$100,000 but less than $250,000	100	1.8	16,548,981	23.3
$250,000 but less than $500,000	20	0.4	8,280,936	11.6
$500,000 and over	3	0.1	2,115,190	3.0

[1] Includes abrasive materials valued at $741,875 produced by operators of stone quarries, but not included in the value shown in Table 1.

Although not clearly shown by the statistics, it is nevertheless true that there exists in the stone industry the same tendency toward the concentration of capital and the formation of stock companies as in other branches of trade, though possibly not to the same extent. This is due not altogether to the desire for combination with a view to controlling trade, but in part at least to a change which has taken place in the character of the industry. The introduction of machinery, often of an expensive type, for both quarrying and dressing, renders necessary a larger initial outlay than in the earlier days of the industry when hand labor alone was employed. The fact, too, that the quarrier in many cases now contracts not merely to furnish the stone, but to furnish it cut and ready for its definite position in the structure, even if he does not contract to set it in place as well, involves a larger capitalization and supply of available funds.

Of the operators shown in the foregoing table 5.7 per cent reported a product valued at $50,000 or more, the value of their combined product constituting 57 per cent of the total; 94.3 per cent reported a product valued at less than $50,000, their combined value of product constituting 43 per cent of the total.

Employees and wages.—The following table shows the average number of wage-earners employed each month:

TABLE 4.—*Average number of wage-earners employed during each month: 1902.*

MONTH.	Wage-earners.
January	49,859
February	50,216
March	60,019
April	72,695
May	79,029
June	81,622
July	83,313
August	83,907
September	82,811
October	79,809
November	70,852
December	59,740

The minimum number, 49,859, was reported for January, and the maximum, 83,907, for August. The variation in the numbers employed during the summer and winter months is readily explained when it is remembered that quarrying is an outdoor pursuit and the severity of the northern winters practically puts a stop to all building and outdoor work. The comparatively recent developments in the Southern states, where the climatic conditions are less severe, have rendered this discrepancy much less marked than in times past.

In Table 5 the figures for the number of wage-earners at specified daily rates of pay in the several kinds of stone quarries are combined, and the totals for all stone quarries are given for the different classes of employees. In addition to the average number of wage-earners included in each rate group, the percentages which these numbers form of their respective totals are shown.

PLATE I.—QUARRY IN OOLITIC LIMESTONE, BEDFORD, INDIANA.

TABLE 5.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

RATE PER DAY (DOLLARS).	ALL OCCUPATIONS.		ENGINEERS.		FIREMEN.		MACHINISTS, BLACKSMITHS, CARPENTERS, AND OTHER MECHANICS.		QUARRYMEN AND STONECUTTERS.		BOYS UNDER 16 YEARS.		ALL OTHER WAGE-EARNERS.

4.25 and over	149	0.2	2	0.1	.....	.....	2	0.1	135	0.3	.....	.....	10	0.1

[1] Includes 5,963 wage-earners paid in accordance with the amount of work done, for whom average daily earnings are shown.
[2] Less than one-tenth of 1 per cent.

The 71,156 wage-earners shown above as employed in stone quarries constituted almost one-eighth (12.2 per cent) of the total number reported in 1902 by all the mines and quarries of the United States. The rates of pay were somewhat lower for stone quarries than for all minerals combined, the range of wages for the bulk (79.9 per cent) of those employed in stone quarries having been from $1 to $2.24, while of the total for all minerals 80.8 per cent received between $1 and $2.74 per day. The difference in wages is more clearly shown, perhaps, in the following comparison: When the figures for all minerals are combined it is found that 57.2 per cent of the total number were paid $2 per day or over, while 42.8 per cent were paid less than $2. In stone quarries, on the other hand, only 30.4 per cent of the wage-earners received $2 per day or over, 69.6 per cent of them having been paid less than $2.

Of the 71,156 wage-earners 49,945 (about seven-tenths) were returned as quarrymen and stonecutters. The greatest concentration of these wage-earners was between rates $1 and $2.24, 79.3 per cent of the total number being included. The next four groups, including those who received from $2.25 to $3.24 per day, constituted 15.7 per cent of the total number. Thus it is seen that 95 per cent of the quarrymen and stonecutters were paid between $1 and $3.24 per day.

The total number of engineers employed in stone quarries in 1902 was 2,540, the range of wages for 80.1 per cent of them being from $1.50 to $2.74 per day. There were 933 firemen reported, 83 per cent of whom received between $1.25 and $2.24 per day. About one-third of all the engineers are included in the single rate group, $2 to $2.24, while 35.5 per cent of the firemen are included in the group, $1.75 to $1.99. There is less concentration in the figures for machinists and other mechanics, the range of wages for 2,780 of them—93.4 per cent of the total number—being from $1.25 to $3.24 per day.

The number of boys under 16 years employed in stone quarries was 731, only 1 per cent of the total number of wage-earners. Of these boys, 69 were paid less than 50 cents a day and 647 were paid between 50 cents and $1.24.

Under the head of "all other wage-earners" are included 14,031 employees, more than three-fourths of whom received from $1 to $1.74 per day and 16.7 per cent received from $1.75 to $2.24.

Supplies, materials, and miscellaneous expenses.—As shown in Table 37, the total amount expended for supplies and materials was $10,739,736. Of this amount, $5,403,912, or 50.3 per cent, was expended in quarrying limestones and dolomites; $2,493,065, or 23.2 per cent, in quarrying siliceous crystalline rocks; $1,298,190, or 12.1 per cent, in quarrying sandstones and quartzites; $825,822, or 7.7 per cent, at marble quarries; $680,361, or 6.3 per cent, at slate quarries; and $38,386, or four-tenths of 1 per cent, in connection with the production of silica sand.

Miscellaneous expenses amounted to $3,976,865, of which total $1,156,754, or 29.1 per cent, was paid for royalties and rent of quarrying plants, and $2,820,111, or 70.9 per cent, for rent of offices, taxes, and other sundries.

Mechanical power.—The total primary power reported aggregated 178,878 horsepower, of which 167,744, or 93.8 per cent, was applied through 4,265 steam engines, and 1,378, or seven-tenths of 1 per cent, through 92 gas or gasoline engines. Fifty-six water wheels furnished 6,731 horsepower, or 3.8 per cent; under "other power," 2,114 horsepower, or 1.2 per cent, was reported; and 911 horsepower, or five-tenths of 1 per cent, was rented from other establishments.

There were, in addition, 97 electric motors owned by the operators reporting them, having a total horsepower of 3,521. Of these, 35 with a horsepower of 769 were used in the production of limestones and dolomites; 32 with 2,220 horsepower, in the production of marble; and 23 with 442 horsepower, in the production of siliceous crystalline rocks.

Production.—The value of the annual production of all classes of stone from 1890 to 1902 is shown in the following table:

TABLE 6.—*Value of annual production of stone: 1890 to 1902.*[1]

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	Value of product.	YEAR.	Value of product.
1890	$53,035,620	1897	$36,070,651
1891	47,294,746	1898	38,441,354
1892	48,721,625	1899	44,090,670
1893	33,985,573	1900	48,008,739
1894	37,065,030	1901	60,275,762
1895	34,688,816	1902	[2]69,830,351
1896	31,346,171		

[1] Exclusive of glass sand, which was not reported by the Geological Survey during the years here shown except in 1902, when it was not included with stone.

[2] Exclusive of limestone, valued at $210,798, used in the manufacture of cement.

The values increased and decreased alternately from 1891 to the close of 1895, and there was a further decrease in 1896, when the lowest value was reported. Since 1896 there has been a steady increase. These fluctuations of value were distributed through all classes of stone.

Discussing the period covered by this table, a decline in the production of granite, limestone, and sandstone began in 1891. The production of slate declined in 1893, but increased a little in 1894. The production of marble fell off in 1893. The return to more prosperous conditions began in 1897, and by 1902 the earlier output had been equaled or exceeded for all classes of stone but sandstones and quartzites, the value of which for 1902 was still below its value for 1890.

Table 37 presents detailed statistics of all classes of stone for 1902.

CLASSIFICATION AND OCCURRENCE.

The matter of the classification of such rocks as are here considered has from the very beginning been one of difficulty, and one which has not yet been solved in a thoroughly satisfactory manner. As a compromise between the minute subdivisions desired by the scientists and the extremely general and often erroneous classification of the quarrymen, the following division has been adopted, which is essentially that followed in 1880:

1. Limestones and dolomites.—These are all sedimentary and bedded rocks, composed essentially of lime carbonate, or the mixed carbonates of lime and magnesia. Such have been found to pass into each other by insensible gradations, certain quarries in the states of the Mississippi valley producing at the same time material which, if classed on purely chemical grounds, would be relegated to both divisions. Obviously a too close adherence to scientific principles would lead to confusion, and hence all are here grouped together.

2. Marble.—Here are included stones identical in composition with those noted under limestones and dolomites, but which through changes, mainly physical, have come to possess properties rendering them desirable for high-grade building or ornamental work. As with the last, they are variable in composition. The marbles of the Rutland, Vt., area, for instance, are largely limestone, while those of the Berkshire county, Mass., area are largely dolomite. With the marbles are also included a small series of serpentinous rocks, which are likewise utilized for decorative purposes.

3. Sandstones and quartzites.—The rocks here brought together are composed essentially of consolidated sands. They are made over, as it were, from the detritus of preexisting rocks. Those classed as "quartzites" are sandstones which have been rendered more or less crystalline through the deposition of silica between the original sand particles, as is the case with the "jasper" of Sioux Falls, S. Dak., or the Potsdam sandstone of St. Lawrence county, N. Y. The tuffs and other volcanic fragmental rocks are also here included.

4. Silica sand.—This is crushed sandstone, used in the manufacture of glass and for other purposes.

5. Siliceous crystalline rocks.—Here are included the true granites and syenites, together with the trappean rocks, such as are often designated as black granites; the gneisses, or so-called striped or bastard granites; the mica schists; and melaphyre, basalt, andesite, and other volcanic rocks.

6. Slate.—This is an argillaceous rock, which, through compression and shearing, has been more or less metamorphosed and rendered fissile, by virtue of which property it may be split into sheets suitable for roofing and other purposes.

Occurrence.—In this connection the following statement relative to the possible resources of the various states of the Union and their present development is not without interest. The list shows the rocks which are known to occur in each state in quantities sufficient for quarrying. The names in small capitals indicate those which were actually quarried during 1902.

PLATE II.—GENERAL VIEW OF STONE YARDS AND WORKS OF THE VERMONT MARBLE COMPANY, PROCTOR, VERMONT.

STATE OR TERRITORY.	Present and prospective resources.
Alabama	Granite, LIMESTONE, MARBLE, SANDSTONE, slate.
Arizona	Dolomite, GRANITE, onyx marble, SANDSTONE, trappean rocks, volcanic rocks, and tuffs.
Arkansas	ELAEOLITE SYENITE, GRANITE, LIMESTONE, marble, SANDSTONE, SLATE.
California	GRANITE, LIMESTONE, MARBLE, SANDSTONE, SLATE, TRAPPEAN ROCKS, VERD ANTIQUE MARBLE, VOLCANIC ROCKS, and TUFFS.
Colorado	GRANITE, LIMESTONE, marble, QUARTZITE, SANDSTONE, TRAPPEAN ROCKS, VOLCANIC ROCKS, and TUFFS.
Connecticut	DIABASE, GNEISS, GRANITE, LIMESTONE, MARBLE, SANDSTONE, verd antique marble.
Delaware	GABBRO, GNEISS, limestone, quartzite, serpentine.
Florida	LIMESTONE (shell and oolitic).
Georgia	GNEISS, GRANITE, LIMESTONE, MARBLE, SANDSTONE, SLATE, VERD ANTIQUE MARBLE.
Idaho	Dolomite, GRANITE, LIMESTONE, marble, SANDSTONE, TRAPPEAN ROCKS, volcanic rocks, and tuffs.
Illinois	DOLOMITE, LIMESTONE, SANDSTONE.
Indian Territory	Dolomite, GRANITE, LIMESTONE, sandstone.
Indiana	DOLOMITE, LIMESTONE, SANDSTONE.
Iowa	DOLOMITE, LIMESTONE, SANDSTONE.
Kansas	DOLOMITE, LIMESTONE, SANDSTONE.
Kentucky	DOLOMITE, LIMESTONE, SANDSTONE.
Louisiana	Limestone, sandstone.
Maine	GNEISS, GRANITE, LIMESTONE, sandstone, SLATE, TRAPPEAN ROCKS, verd antique marble.
Maryland	GNEISS, GRANITE, LIMESTONE, MARBLE, SANDSTONE, SLATE, verd antique marble.
Massachusetts	GNEISS, GRANITE, LIMESTONE, MARBLE, SANDSTONE, slate, TRAPPEAN ROCKS, VERD ANTIQUE MARBLE.
Michigan	DOLOMITE, gneiss, GRANITE, LIMESTONE, SANDSTONE, slate.
Minnesota	DOLOMITE, gneiss, GRANITE, LIMESTONE, quartzite, SANDSTONE, slate.
Mississippi	Limestone, sandstone.
Missouri	DIABASE, DOLOMITE, GRANITE, LIMESTONE, SANDSTONE.
Montana	DOLOMITE, gneiss, GRANITE, LIMESTONE, MARBLE, SANDSTONE, trappean rocks, volcanic rocks, and tuffs.
Nebraska	DOLOMITE, LIMESTONE, SANDSTONE.
Nevada	Dolomite, granite, limestone, marble, SANDSTONE, slate, trappean rocks, VOLCANIC ROCKS, and tuffs.
New Hampshire	GNEISS, GRANITE, limestone, slate.
New Jersey	DIABASE, DOLOMITE, GNEISS, GRANITE, LIMESTONE, marble, SANDSTONE, SLATE.
New Mexico	Granite, limestone, MARBLE, SANDSTONE, trappean rocks, verd antique marble, volcanic rocks, and tuffs.
New York	DOLOMITE, GNEISS, GRANITE, LIMESTONE, MARBLE, NORITE, SANDSTONE, SLATE, TRAPPEAN ROCKS, verd antique marble.
North Carolina	Dolomite, GNEISS, GRANITE, LIMESTONE, marble, SANDSTONE, serpentine, slate, trappean rocks.
North Dakota	Dolomite, limestone, sandstone.
Ohio	DOLOMITE, LIMESTONE, SANDSTONE.
Oklahoma	DOLOMITE, LIMESTONE, SANDSTONE.
Oregon	DOLOMITE, GRANITE, LIMESTONE, SANDSTONE, trappean rocks, volcanic rocks, and tuffs.
Pennsylvania	DIABASE, DOLOMITE, GNEISS, GRANITE, LIMESTONE, MARBLE, SANDSTONE, SLATE, SERPENTINE.
Rhode Island	Dolomite, GNEISS, GRANITE, limestone.
South Carolina	Gneiss, GRANITE, limestone.
South Dakota	LIMESTONE, QUARTZITE, SANDSTONE.
Tennessee	Granite, LIMESTONE, MARBLE, SANDSTONE slate.
Texas	GRANITE, LIMESTONE, marble, SANDSTONE, slate, trappean rocks, volcanic rocks and tuffs.
Utah	GRANITE, LIMESTONE, MARBLE, ONYX MARBLE, SANDSTONE, trappean rocks, volcanic rocks, and tuffs.
Vermont	DOLOMITE, gneiss, GRANITE, LIMESTONE, MARBLE, SLATE, verd antique marble.
Virginia	Diabase, DOLOMITE, gneiss, GRANITE, LIMESTONE, marble, SANDSTONE, SLATE.
Washington	GRANITE, LIMESTONE, MARBLE, SANDSTONE, trappean rocks, VERD ANTIQUE MARBLE, volcanic rocks, and tuffs.
West Virginia	Calcareous tufa, LIMESTONE, SANDSTONE, travertine.
Wisconsin	DOLOMITE, gneiss, GRANITE, LIMESTONE, SANDSTONE.
Wyoming	Granite, LIMESTONE, marble, SANDSTONE, trappean rocks, volcanic rocks, and tuffs.

A critical examination of the foregoing statement shows that the siliceous crystalline rocks, marbles, and slates are limited in their distribution mainly to the areas east of the Appalachians, those bordering along the Great Lakes, and those west of the front range of the Rocky mountains. The sandstones and limestones, on the other hand, are more widely distributed, although found best developed for quarry purposes in the great interior regions of the Mississippi valley. These points will be brought out in greater detail in the discussion of the various classes of stone.

The importance of a study of the stone resources of the various states is being gradually recognized, and reports covering the subject with more or less completeness were issued by Ohio and Minnesota in 1884, New York in 1888, Arkansas in 1890, Indiana and Pennsylvania in 1896, Maryland and Wisconsin in 1898, and Georgia in 1902.

LIMESTONES AND DOLOMITES.

The rocks brought together here differ from those included under the head of marble not so much in composition as in physical properties. They represent the limestones and dolomites of the ordinary unmetamorphosed type, such as are lacking in qualities rendering them susceptible for a high grade of ornamental work, but suitable, it may be, for building. As will be noted, a large proportion of the material quarried under this name was utilized for other than structural purposes.

Table 7 presents comparative statistics for this industry for 1902 and 1889.

TABLE 7.—*Comparative summary: 1902 and 1889.*

	1902	1889
Number of quarries	3,246	1,954
Number of operators	3,137	[1]
Salaried officials, clerks, etc.:		
Number	2,231	[2] 433
Salaries	$1,843,747	[3]
Wage-earners:		
Average number	31,547	[2] 30,211
Wages	$14,750,638	[3] $10,121,985
Contract work	$36,381	[1]
Miscellaneous expenses	$1,440,081	$743,483
Cost of supplies and materials	$5,403,912	$4,227,246
Value of product	[4] $30,441,801	$19,095,179

[1] Not reported.
[2] Foremen included as wage-earners.
[3] Salaries included in wages.
[4] The report of the United States Geological Survey does not include limestone, valued at $210,798, consumed in the manufacture of cement.

Statistics for 1880 are not suitable for comparison, since the census returns for that year excluded all material not used for building purposes and did not differentiate between limestones and marbles. (See Table 12.)

The number of quarries has increased by 1,292, or 66.1 per cent, since 1889, the amount paid in salaries and wages has increased $6,472,400, or 63.9 per cent, and the value of products $11,346,622, or 59.4 per cent. Of the 3,137 operators reported for 1902, 2,282 were individuals, 480 firms, 344 incorporated companies, and 31 cooperative associations and other forms of organization.

In 1902 development work was reported at 3 quarries—2 in California and 1 in Wisconsin. Four salaried officials, clerks, etc., received $2,800, and there were 33 wage-earners to whom $10,430 was paid in wages. Miscellaneous expenses were $1,075, and supplies and materials cost $5,250.

Employees and wages.—In 1902 the 31,547 wage-earners formed 93.4 per cent of the total number of employees and the $14,750,638 paid them as wages was 88.9 per cent of the total amount expended in salaries and wages. In addition, $36,381 was paid for contract work, which gave employment to 137 persons.

The following table presents the average number of wage-earners employed during each month:

TABLE 8.—*Average number of wage-earners employed during each month: 1902.*

MONTH.	Wage-earners.
January	22,581
February	22,410
March	27,638
April	33,077
May	35,084
June	35,959
July	36,447
August	36,965
September	36,621
October	34,947
November	30,604
December	26,231

The greatest number of wage-earners, 36,965, was reported for August, and the least, 22,410, for February; thus the variation was 14,555, or 46.1 per cent of the yearly average number, 31,547. This yearly average is 44.3 per cent of the total for all classes of stone.

The following table shows the number of wage-earners at certain specified daily rates of pay by occupations and also the percentages which these numbers form of the total number in the class:

TABLE 9.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

RATE PER DAY (DOLLARS).	ALL OCCUPATIONS.		ENGINEERS.		FIREMEN.		MACHINISTS, BLACKSMITHS, CARPENTERS, AND OTHER MECHANICS.		QUARRYMEN AND STONECUTTERS.		BOYS UNDER 16 YEARS.		ALL OTHER WAGE-EARNERS.

[1] Includes 3,772 wage-earners paid in accordance with the amount of work done, for whom average daily earnings are shown.
[2] Less than one-tenth of 1 per cent.

As shown by the above table, 28,772 wage-earners, 91.2 per cent of the total number, received between $1 and $2.24 per day. Of the quarrymen and stonecutters, 20,430, or 92.7 per cent, are included between the same rates. There is little need for highly skilled workmen in limestone quarries, and consequently the rates paid are practically the same as those paid in all trades for unskilled labor.

The rates paid to engineers and to machinists and other mechanics were somewhat higher than those for other wage-earners; 83.7 per cent of the engineers received from $1.50 to $2.74 per day, and 76.9 per cent of the machinists and other mechanics were included between the same rates. The range of wages for over three-fourths (78.5 per cent) of the firemen reported was between $1.25 and $1.99 per day.

In all, only 258 boys under 16 years were reported, which number is less than 1 per cent of the total number of wage-earners. Of these boys, 16 were paid less than 50 cents a day, and 239 were paid from 50 cents to $1.24. The boys reported were not employed in any one locality. There were 51 in Indiana, 36 in Virginia, and 33 in Pennsylvania. The others were distributed in small groups through a large number of states.

Under "all other wage-earners" are included 7,020 men, 22.3 per cent of the total number. The rates paid to these employees differ very little from those for quarrymen and stonecutters. About four-fifths (5,628, or 80.2 per cent) of those classed as "all other wage-earners" received between $1 and $1.74 per day, and 1,103, or 15.7 per cent, received from $1.75 to $2.24.

Supplies, materials, and miscellaneous expenses.—Supplies and materials, of which a large amount was fuel for lime burning, cost $5,403,912. The amount paid for royalties and rent of quarrying plants was $422,693, or 29.4 per cent of the total miscellaneous expenses; $1,017,388, or 70.6 per cent, was paid for rent of offices, taxes, insurance, and other sundries.

Mechanical power.—The total primary power reported aggregated 64,500 horsepower, of which 61,547, or 95.4 per cent, was applied through 1,703 steam engines; 1,031, or 1.6 per cent, through 59 gas or gasoline engines; and 502, or eight-tenths of 1 per cent, by 15 water wheels. Under "other power" 1,221 horsepower, or 1.9 per cent, was reported. There were in addition 35 electric motors with an aggregate horsepower of 769. Rented horsepower aggregated 199, or three-tenths of 1 per cent.

Production.—The following table shows the annual value of the production of limestones and dolomites from 1890 to 1902:

PLATE III.—INTERIOR VIEW OF MARBLE QUARRY, PROCTOR, VERMONT.

TABLE 10.—*Value of annual production of limestones and dolomites: 1890 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	Total.	YEAR.	Total.
1890	$19,095,179	1897	$14,822,661
1891	15,792,000	1898	16,039 056
1892	18,342,000	1899	18,757,963
1893	13,947,223	1900	20,354,019
1894	16,512,904	1901	26,406,897
1895	15,308,755	1902	30,441,801
1896	13,022,637		

There was a decrease in value of product from 1890 to 1891, an increase in 1892, a decrease again in 1893, with an advance in 1894 and a slight falling off in 1895. In 1896 the retrograde movement in value reached its lowest point. The increase since then has been constant.

The following table shows the value of the annual production of limestones and dolomites, classified by uses, 1894 to 1902:

TABLE 11.—*Limestones and dolomites, classified by uses: 1894 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	VALUE OF PRODUCT.		Blast furnace flux.	All other uses.
	Building.	Made into lime.		
1894	$7,382,055	$8,610,607	$520,242	[1]
1895	7,350,248	6,588,822	1,369,685	[1]
1896	5,491,227	6,327,900	1,203,510	[1]
1897	7,029,295	6,390,487	1,402,879	[1]
1898	4,154,158	6,886,549	1,834,090	$3,164,259
1899	5,075,158	6,983,067	2,580,799	4,118,939
1900	4,330,706	6,797,496	3,687,394	5,538,423
1901	5,219,310	8,204,054	4,659,836	8,323,697
1902	5,563,084	9,335,618	5,271,252	10,271,847

[1] Not reported.

The total value of the output for 1902 was $30,441,801, of which only $5,563,084 was utilized for building purposes, the remainder being used for flagging, curbing, lime burning, roadmaking, rubble, riprap, flux, etc. The largest single item, which amounted to $9,335,618, was for lime burning, and the second, that of $5,271,252, was for flux in metallurgical operations. A large amount was also used for macadam, not so much on account of its suitability as because of its cheapness, the almost complete absence of siliceous, and especially trappean, rocks from the Mississippi valley states necessarily limiting the selection to either limestone or sandstone.

The detailed statistics of this industry for 1902 are shown in Table 38.

Occurrence.—Rocks of this type, though occurring in every state of the Union, are found in their maximum development in the states of the Mississippi valley, where the agents of metamorphism have exercised but little influence and the rocks have retained their original sedimentary character. In some instances rocks of this class are of a highly fossiliferous nature. Such, however, are not as a rule utilized for building purposes, but rather for lime burning, etc. Those utilized for architectural purposes are principally of the fine grained homogeneous type, such as the dolomitic limestones of Lemont, Ill., or of the oolitic type, such as the stones so extensively developed in the region of Bedford, Ind. These stones work readily under the tool, and when free from injurious constituents are admirably adapted for elaborate structures where much carved work is required. This is especially true of the stone at Bedford, where the conditions are particularly favorable for quarrying, the beds having retained very nearly their original horizontality. The quarry development is extensive, as is evident from the illustration given in Plate I. The ease with which these stones are removed by the aid of machinery from the quarry bed, and the readiness with which they may be worked, as well as their satisfactory colors, have rendered them general favorites for building purposes and they have found their way into the larger cities all over the country.

MARBLE.

The stones here included under the head of marble are mainly those composed of carbonate of lime, or the mixed carbonates of lime and magnesia, in other words, limestones and dolomites, which, owing to their color and physical properties, are suitable for high-grade building and ornamental purposes.

It should be stated that no sharp line can be drawn between what is popularly known as marble and the common limestones and dolomites, as what is or what is not suitable for decoration must depend largely upon the taste of the individual. The stones here included are, however, those which are sold as marble, and in two instances serpentinous rock—the so-called verd antique marble.

The following table is a comparative summary of the marble industry from 1870 to 1902.

TABLE 12.—*Comparative summary: 1902, 1889, 1880, and 1870.*

	1902	1889	1880[1]	1870
Number of quarries	83	103	616	[2]
Number of operators	75	74	[2]	[3]22
Salaried officials, clerks, etc.:				
Number	352	[4]96	[2]	[2]
Salaries	$341,021	[5]	[2]	[2]
Wage-earners:				
Average number	4,070	[4]4,433	[6]15,646	795
Wages	$2,212,640	[5]$1,809,211	[2]	$442,270
Miscellaneous expenses	$382,877	$210,272	[2]	[2]
Cost of supplies and materials	$825,822	$655,586	[7]$61,408	$36,916
Value of product	$5,044,182	$3,488,170	$6,856,681	$804,300

[1] Includes limestones and dolomites; statistics for marble can not be separated.
[2] Not reported.
[3] Establishments.
[4] Foremen included as wage-earners.
[5] Salaries included in wages.
[6] Greatest number employed.
[7] Value of explosives.

In the published statistics of the census of 1880 no discrimination was made between the two classes of rocks. The writer, knowing the character of the output of the various quarries, estimated the value pro-

duced that year at $2,044,225 which, it will be observed by reference to Table 12, was increased to $3,488,170 in 1889 and to $5,044,182 in 1902.

There were 83 quarries in operation during 1902 with 352 salaried officials, clerks, etc., and 4,070 wage-earners, while in 1889 there were 103 quarries with 254 salaried officials, clerks, etc., and 4,275 wage-earners. The decrease in the number of active quarries is very probably due to the consolidation and incorporation of companies. The apparent decrease in the number of wage-earners may be accounted for by the different methods pursued by the several censuses in obtaining the average number employed; also by the introduction of machinery and improved methods in quarrying. That this decrease is only apparent, seems all the more probable when it is taken into consideration that both the amount paid as wages and the value of the marble produced increased to a marked degree during each census year.

There were 10 quarries reported as being developed by as many operators, 8 of whom were incorporated companies and had issued capital stock and bonds to the amount of $5,031,500. Six of these quarries were located in Washington, and there was 1 each in California, Kentucky, Montana, and Utah. These gave employment to 7 salaried officials and 25 wage-earners, who received $22,405 in salaries and wages. From these 10 quarries supplies and materials to the amount of $5,218, and miscellaneous expenses to the amount of $2,550, was reported.

There were 114 quarries reported idle during 1902 and these were controlled by 114 operators, 53 of whom were incorporated companies. Capital stock and bonds were issued to the amount of $9,127,250 by 25 of these companies.

Capital stock of incorporated companies.—Of the 75 operators of productive quarries, 45 were incorporated companies. Forty-three of these made returns showing a capital stock of $17,609,900 and a bonded indebtedness of $2,708,500. The details are shown in the following table:

TABLE 13.—CAPITALIZATION OF INCORPORATED COMPANIES: 1902.

	United States.	California.	Georgia.	Massachusetts.	New York.	Pennsylvania.	Tennessee.	Vermont.	Washington.	All other states and territories.[1]

[1] Includes incorporated companies distributed as follows: Alabama, 1; Maryland, 2; New Mexico, 1.

PLATE IV.—INTERIOR VIEW OF MARBLE QUARRY, RUTLAND, VERMONT.

The value of the capital stock and bonds issued by the Vermont companies constitutes 44.9 per cent of the total; by the Georgia companies, 20.7 per cent; by the Washington companies, 17.2 per cent; and by the Tennessee companies, 5.8 per cent. The par value of the capital stock issued was 86.3 per cent of the total authorized. The dividends paid amounted to 3.8 per cent of the total stock on which they were declared.

The production of the mines operated by the 45 incorporated companies, including the 2 not reporting details of capitalization, was valued at $4,469,791, or 88.6 per cent of the total value.

Employees and wages.—The 4,070 wage-earners constituted 92 per cent of the salaried employees and wage-earners, and their wages were 86.6 per cent of the total salaries and wages. Vermont led with 51 per cent of the wage-earners; Tennessee was second, with 14.9 per cent; New York was third, 11.5 per cent; and Georgia was fourth, with 7.6 per cent.

The following table shows the average number of wage-earners employed each month:

TABLE 14.—*Average number of wage-earners employed during each month: 1902.*

MONTH.	Wage-earners.
January	3,574
February	3,618
March	3,880
April	4,090
May	4,316
June	4,184
July	4,186
August	4,228
September	4,430
October	4,275
November	4,119
December	3,940

September was the month during which the largest number of wage-earners, 4,430, was employed, although the variation during the year was not great. The smallest number, 3,574, was employed in January.

The following table shows the distribution of wage-earners according to daily rates of pay, by occupations:

TABLE 15.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

RATE PER DAY (DOLLARS).	ALL OCCUPATIONS.		ENGINEERS.		FIREMEN.		MACHINISTS, BLACKSMITHS, CARPENTERS, AND OTHER MECHANICS.		QUARRYMEN AND STONECUTTERS.		BOYS UNDER 16 YEARS.		ALL OTHER WAGE-EARNERS.

[1] Includes 17 wage-earners paid in accordance with the amount of work done, for whom average daily earnings are shown.
[2] Less than one-tenth of 1 per cent.

The range of wages for employees in marble quarries was very wide. In 1902 there were 84 wage-earners getting less than $1 per day, and 105 receiving $4.25 and over. Between these extremes the employees were distributed in comparatively small groups, except between the rates from $1 to $1.74, where 58.5 per cent of the total number were included.

The quarrymen and stonecutters constituted 61.7 per cent of the total number of wage-earners reported. The wide range noticeable in the figures for all occupations combined is due almost entirely to the great variation in the rates paid to the quarrymen and stonecutters. More than half (59.3 per cent) of the total number were included in the three wage groups from $1 to $1.74, but most of the remainder were distributed in small groups from $1.75 to $4.25 and over. The difference between the wages paid to quarrymen and those paid to highly skilled stonecutters is very apparent in the figures presented.

The range of wages for the bulk of the engineers was from $1 to $2.74 per day, 91.1 per cent of the total number being included between those rates. Of the firemen nine-tenths received between $1 and $2.49, while 91.1 per cent of the machinists and other mechanics received from $1.25 to $2.74. Of the 22 boys under 16 years reported, 20 were paid less than 75 cents a day.

Under "all other wage-earners" are included 1,018 workmen. Almost six-tenths of these—59.3 per cent—were employed at rates between $1.25 and $1.74. Of the others 10.2 per cent received between 75 cents and $1.24 per day, and 27 per cent received from $1 75 to $2.74.

Supplies, materials, and miscellaneous expenses.—The cost of supplies and materials was reported as $825,822, which was the largest item of expense other than wages. Of the $382,877 expended for miscellaneous expenses, $317,492, or 82.9 per cent, was paid for rent of offices, taxes, insurance, interest, and other sundries, and $65,385, or 17.1 per cent, was expended for royalties and rent of quarrying plant.

Mechanical power.—The total horsepower reported was 14,286, of which 10,748, or 75.2 per cent, was applied through 191 steam engines, and 3,413, or 23.9 per cent, was supplied by 15 water wheels. The remainder was classified as "other power." The total power was reported by 60 operators, Vermont leading with 53.1 per cent.

Production.—The annual production of marble from 1890 to 1902 is shown in the following table:

TABLE 16.—*Value of annual production of marble: 1890 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	Total.	YEAR.	Total.
1890	$3,488,170	1897	$3,870,584
1891	3,610,000	1898	3,629,940
1892	3,705,000	1899	4,011,681
1893	2,411,000	1900	4,267,253
1894	3,199,585	1901	4,965,699
1895	2,825,719	1902	5,044,182
1896	2,859,136		

The gradual increase shown in 1890, 1891, and 1892 was followed by the great depression of 1893. An increase of $788,585 was shown for 1894, while in 1895 the value of production decreased to $2,825,719. This period of fluctuation was followed by a steady increase, except in 1898, until, in 1902, the value of product reached $5,044,182.

The following table shows the value of the annual production of marble, classified by uses, 1896 to 1902:

TABLE 17.—*Marble, classified by uses: 1896 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	VALUE OF PRODUCT.					
	Rough, all uses.	Dressed.				All other uses.
		Building.	Monumental.	Ornamental.	Interior decoration.	
1896	$583,690	$1,036,163	$813,146	$65,365	$329,804	$30,968
1897	477,856	1,074,646	1,547,469	9,010	576,983	184,620
1898	690,240	968,353	1,613,742	23,904	304,714	28,987
1899	640,535	1,176,208	1,650,155	92,942	389,040	62,801
1900	491,813	1,080,969	2,019,474	13,754	555,092	106,151
1901	591,667	1,236,023	1,948,892	126,576	1,008,482	54,059
1902	2,276,629	1,038,102	956,870	7,300	679,913	85,368

The following table shows the value of product of the principal marble producing states for 1902 and 1889, and ranks them according to these values:

TABLE 18.—*Production of marble, by principal states ranked by value of product: 1902 and 1889.*

STATE.	1902		1889	
	Value.	Rank.	Value.	Rank.
Vermont	$2,628,164	1	$2,169,560	1
Georgia	660,517	2	196,250	4
New York	577,298	3	354,197	3
Tennessee	518,256	4	419,467	2
Massachusetts	165,489	5	.....	.....
Pennsylvania	160,423	6	.....	.....
California	92,298	7	87,030	5
Washington	61,176	8	.....	.....

In the number of quarries and value of output Vermont ranked first among the marble producing states in 1902. This has been the case since the very inception of the industry, though the proportional difference in output is being continually lessened as developments are made in other states. While the value of the product of Vermont has increased rather than diminished, the state in 1902 produced only 52.1 per cent of the output of the United States instead of 62.2 per cent, as in 1889. Other differences are equally marked. These are due mainly to the remarkable developments in Georgia, whereby the product was increased from $196,250 in 1889 to $660,517 in 1902; to the reopening of the long abandoned quarries in Berkshire county, Mass.; to developments near Avondale, in Chester county, Pa., in Adams and Stevens counties, Wash., and minor developments in Montana and Utah.

Occurrence.—The matter of the geographic distribution of marbles throughout the United States is of considerable economic importance. It will be noted by reference to Table 39 that a very large proportion of them are to be found in states bordering along the Appalachian mountain system. Recent developments show that materials of the same nature exist in the states west of the front range of the Rocky mountains, but thus far little more than development work has been done except in California and Washington. The entire region lying between the Appalachians and the front range of the Rocky mountains to the westward is quite unsupplied with anything that can properly be designated as marble, the geological conditions which were instrumental in producing the necessary alteration from the common limestone having here been inoperative.

With reference to the above distribution the following statement as to color, texture, and uses may be added, beginning with the most northerly of the marble producing states:

Vermont.—Marbles of a holocrystalline granular structure, varying from pure white to white veined with blue-gray and greenish to dark clouded blue-gray, occur in a somewhat interrupted belt extending throughout the entire length of the western part of the state. The

PLATE V.—INTERIOR VIEW OF MARBLE QUARRY NEAR TATE, PICKENS COUNTY, GEORGIA.

quarry industry is developed to the greatest extent in Rutland county. Views showing the present condition of quarries at West Rutland and Proctor are given in Plates II, III, and IV. The stone is used for building, monumental, and decorative work. Chocolate, red, and variegated forms, used for tiling and interior decoration, are found in the vicinity of Mallet bay.

Massachusetts.—Holocrystalline rather coarsely granular building marbles of a white color are found in the various towns of Berkshire county.

New York.—Coarsely crystalline white and grayish dolomitic marbles, which are used mainly for building purposes, occur in Westchester and St. Lawrence counties.

Pennsylvania.—Holocrystalline granular marbles of a white and gray color, used mainly for building purposes, come from Montgomery and Chester counties.

Maryland.—Holocrystalline granular white marbles, used for general building purposes, are quarried in Baltimore county.

Georgia.—Holocrystalline coarsely granular white clouded and pink marbles, used mainly for building but also for interior decoration and monumental work, occur in Cherokee and Pickens counties. (See Plate V.)

Tennessee.—Pink, gray, and chocolate and white mottled stone, used almost wholly for interior decoration, is found in the region about Knoxville and Rogersville, in eastern Tennessee.

Washington.—A peculiar green or green-white mottled stone, consisting of an admixture of lime and magnesian carbonates, brucite, and serpentine, is being developed near Spokane, and worked into various art objects, such as vases, urns, and bowls, an entirely new departure in marble work.

A very large proportion of the marbles used for interior decoration, and, indeed, almost the entire supply of the verd antiques, are still imported, Italy, Africa, and Greece furnishing the largest amounts, although of late a considerable quantity has been brought from Norway. This importation is due in part to the more desirable quality of the material, and in part to the cheapness of foreign labor and low ocean freight rates.

A detailed summary showing the statistics of the marble industry for 1902 is given in Table 39.

SANDSTONES AND QUARTZITES.

Under the head of sandstones and quartzites, is included a widely variable series of rocks, composed, as the name suggests, largely of siliceous sand, which, through the influence of cementing materials or natural compression, has become sufficiently indurated to be utilized for building purposes. With them are also included certain rocks of similar origin but which, through the deposition of a siliceous cement, have become partially recrystallized and are known as quartzites. The so-called "Potsdam sandstone" of New York and the "jasper" of Sioux Falls, S. Dak., are good examples of this latter type. Here, too, are included the "bluestones" of New York and Pennsylvania, so widely used for flagging purposes, and the volcanic tuffs.

The following table presents comparative statistics for this industry for 1902, 1889, and 1880.

TABLE 19.—*Comparative summary: 1902, 1889, and 1880.*

	1902	1889	1880
Number of quarries	1,304	1,020	502
Number of operators	1,211	(1)	(1)
Salaried officials, clerks, etc.:			
Number	847	[2] 260	(1)
Salaries	$713,579	(3)	(1)
Wage-earners:			
Average number	10,448	[2] 18,458	[4] 9,567
Wages	$6,153,060	[3] $6,785,214	(1)
Contract work	$500	(1)	(1)
Miscellaneous expenses	$878,780	$641,874	(1)
Cost of supplies and materials	$1,298,190	$1,311,789	[5] $27,571
Value of product	$10,601,171	[6] $12,505,663	$4,780,391

[1] Not reported.
[2] Foremen are included as wage-earners.
[3] Salaries are included in wages.
[4] Greatest number employed.
[5] Value of explosives.
[6] Includes bluestone, valued at $939,694, purchased by wholesale dealers.

There has been an actual increase in the number of quarries in operation, but this is due to the opening of small rural quarries, and is not accompanied by an increase in any of the expenditures except those classed as miscellaneous.

Employees and wages.—The total number of salaried officials and wage-earners was 11,295, the wage-earners contributing 10,448, or 92.5 per cent of this number. Their wages were $6,153,060, or 89.6 per cent of the total salaries and wages.

The following table shows the average number of wage-earners employed during each month:

TABLE 20.—*Average number of wage-earners employed during each month: 1902.*

MONTH.	Wage-earners.
January	5,727
February	5,794
March	7,765
April	10,405
May	12,778
June	13,406
July	13,368
August	13,152
September	12,705
October	11,980
November	10,506
December	7,790

The greatest number given employment for any one month was 13,406 in June; the least number was 5,727 in January. Sandstone quarries can not be operated during severe winter weather, as the stone must be quarried without an excess of moisture or frost, in order that it may weather well.

In the following table the distribution of wage-earners, according to daily rates of pay, is shown for the several classes of employees. The number receiving certain specified rates is given for each class, and also the percentages which these numbers form of the total number in their respective classes:

TABLE 21.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

RATE PER DAY (DOLLARS).	ALL OCCUPATIONS.		ENGINEERS.		FIREMEN.		MACHINISTS, BLACKSMITHS, CARPENTERS, AND OTHER MECHANICS.		QUARRYMEN AND STONECUTTERS.		BOYS UNDER 16 YEARS.		ALL OTHER WAGE-EARNERS.

3.75 to 3.99	26	0.2					3	0.6	23	0.3				
4.00 to 4.24	86	0.8	2	0.4	1	0.4	2	0.4	81	1.1				
4.25 and over	30	0.3							30	0.4				

[1] Includes 822 wage-earners paid in accordance with the amount of work done, for whom average daily earnings are shown.
[2] Less than one-tenth of 1 per cent.

The range of wages for men employed in sandstone and quartzite quarries is not wide. Of the 10,448 wage-earners reported, 7,643, or 73.1 per cent, received between $1.25 and $2.24 per day. A very few, only 3.8 per cent, were paid less than $1.25, and the balance, 2,409, or 23.1 per cent, were distributed in small groups between $2.25 and $4.25. It will be noticed that there was a greater concentration of the several classes of wage-earners at a few rate groups in sandstone and quartzite quarries than in other stone quarries.

More than two-thirds of all the wage-earners were classed as quarrymen and stonecutters, 7,117 men having been reported under that head. More than six-tenths of them (62.3 per cent) were included in the three rate groups between $1.50 and $2.24. Those who received less than $1.50 per day numbered 741, and constituted 10.5 per cent of the total number, while 1,799 men, or 25.4 per cent, were distributed in small groups between $2.25 and $3.74.

The engineers, of whom 529 were reported, show a marked concentration at $2 a day, 236, or 44.6 per cent, being included in the single rate group, $2 to $2.24. For firemen an even greater concentration is shown, but at the next lower rate group; of the 241 firemen reported, 178, or 73.9 per cent, were paid between $1.75 and $1.99 per day. A wider range of wages is indicated by the figures for machinists and other mechanics. For them, too, the greatest concentration occurs in the $1.75 and $2 groups, but 14.9 per cent of them were paid less than $1.75 per day and 13.5 per cent received $3 or over.

Less than 1 per cent of the wage-earners were boys under 16 years, only 76 in all having been reported. Most of these boys were fairly well paid, 69 of them having received between 50 cents and $1.24 per day, and only 4 of them getting less than 50 cents.

Under the head of "all other wage-earners" are included 2,007 men, almost one-fifth of the total number reported. The range of wages for 1,594, or 79.4 per cent, was from $1.25 to $1.99 per day.

Supplies, materials, and miscellaneous expenses.—The comparative ease with which sandstone may be removed from the quarry bed, by the aid of modern machinery, tends largely to reduce the expenditure for supplies and materials, the cost of which in 1902 was $1,298,190. The total amount paid for miscellaneous expenses was $878,780, of which the amount paid for royalties and rent of quarrying plants formed 22.3 per cent, and rent of offices, taxes, insurance, and other sundries, 77.7 per cent.

Mechanical power.—The total primary power reported was 25,652 horsepower. Of this amount 789 steam engines contributed 24,631 horsepower, or 96 per cent; 7 gas or gasoline engines, 72 horsepower, or three-tenths of 1 per cent; 6 water wheels, 885 horsepower, or 3.5 per cent. The remainder was "other power." In addition 6 electric motors, with a total of 60 horsepower, were used during the census year by the operators who generated their own electricity.

Production.—The annual production of sandstones and quartzites from 1890 to 1902 is shown in the following table:

PLATE VI.—FIG. 1. VIEW NEAR WESTERN END OF GREAT CANYON SANDSTONE QUARRY, AMHERST, OHIO.

PLATE VI.—FIG. 2. VIEW OF SANDSTONE QUARRY AT BEREA, OHIO.

TABLE 22.—*Value of annual production of sandstones and quartzites: 1890 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	Total.	YEAR.	Total.
1890	$12,505,663	1897	$4,965,445
1891	10,200,000	1898	5,724,412
1892	9,915,500	1899	5,739,954
1893	5,295,151	1900	[1] 6,471,384
1894	4,855,847	1901	[1] 8,138,680
1895	4,961,314	1902	[1] 10,601,171
1896	4,773,199		

[1] Does not include grindstones and whetstones.

The minimum production for the thirteen years was reached in 1896, when the product was valued at $4,773,199. The maximum was in 1890, when the value of the product was $12,505,663, or $1,904,492 more than the value for 1902.

The following table shows the value of products, classified by uses, from 1899 to 1902:

TABLE 23.—*Sandstones and quartzites, classified by uses: 1899 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	VALUE OF PRODUCT.			
	Building.		Flagging.	All other uses.
	Rough.	Dressed.		
1899	$1,998,032	$2,003,523	[1] $1,487,810	$236,030
1900	1,778,322	2,207,699	[1] 2,071,887	413,476
1901		[2] 4,875,973	1,026,499	2,236,208
1902	3,119,236	2,888,248	1,142,699	3,450,988

[1] Includes curbing. [2] Includes rough building.

Of the $10,601,171 given as the total value of products in 1902, $6,007,484 was the value of the stone used for building purposes, the remainder being the value of the stone disposed of as riprap, rubble, paving, flagging, and crushed stone for road ballast, etc. A comparatively small amount was crushed and utilized as sand for glassmaking, as noted under "silica sand."

A comparison of the figures for 1889 and 1902 shows that the values increased more than elevenfold in Arizona and Texas, about sixfold in Idaho, fivefold in Wyoming, threefold in Arkansas and West Virginia, and twofold or more in California, Minnesota, Montana, Tennessee, and Utah. In 14 states the values decreased during these years. The largest per cents of decrease are as follows: New Mexico, 93; Connecticut, 86; Iowa, 81; Colorado, 70; Missouri, 63; and Washington, 59. There was a falling off of over 30 per cent in New Jersey and Ohio, and for Kansas, Massachusetts, and New York the decrease was between 25 and 30 per cent.

For comparative purposes the following table is given, showing the rank in value of product by states and territories for 1902 and 1889:

TABLE 24.—*Sandstones and quartzites, by principal states and territories ranked by value of product: 1902 and 1889.*

STATE OR TERRITORY.	1902		1889	
	Value.	Rank.	Value.	Rank.
Pennsylvania	$2,800,108	1	$1,986,894	3
Ohio	2,078,754	2	3,046,656	1
New York	1,408,699	3	2,005,740	2
Massachusetts	487,366	4	649,097	6
California	462,328	5	175,598	11
West Virginia	423,532	6	140,687	14
New Jersey	406,726	7	605,859	7
Colorado	366,161	8	1,224,098	4
Minnesota	347,472	9	131,979	15
Wisconsin	207,086	10	183,958	10

A detailed summary showing the statistics of the industry for 1902 is given in Table 40.

Occurrence.—The sandstones are among the most variable and widely distributed of American building material. Those which have been most sought on account of their color and working qualities are the red-brown Triassic stones of the eastern United States, the light-gray to buff Carboniferous stones of the Mississippi valley, of which the so-called "Berea grit" is a familiar type, and the New York and Pennsylvania bluestones, utilized mainly for flagging purposes.

The sandstones are for the most part comparatively easy to work and, next to the granites, have been more generally employed for structural purposes than any other of our natural building materials. They are found interstratified with rocks of all geological horizons from the Cambrian down to the Tertiary and occupying all positions with relation to horizontality. In the mountainous regions the deposits are naturally more or less distorted and occupy more or less inclined positions. In the region of the Mississippi valley, where the geological agencies have been much less violent, the beds retain their original horizontal position and afford admirable facilities for quarry operations upon a large scale. It is upon these beds that some of the largest quarries in the country have been opened. Figures 1 and 2, Plate VI, show the position of the stone and the remarkable natural facilities for extraction as well as the great amount of development which has taken place at Amherst and Berea, Ohio.

SILICA SAND.

Silica or siliceous sand includes not only sand suitable for the manufacture of glass, but also a large quantity designated as engine and furnace sand and sand for other uses, it being impossible to separate the statistics. Of the value of product, $50,811 is for sand produced at regular sandstone quarries, being the waste or scrap stone crushed. In such instances the statistics of salaries, wages, and other expenditures, not being separable, have been included with those for sandstones and quartzites. At the census of 1880, glass sand was separately reported. Thirty-three mines were shown, at which 332 employees received wages amounting to $96,598, and the value of the product was $239,095. At the Eleventh Census, "sand for glass" was included with sandstone.

The following table is a summary for 1902:

TABLE 25.—*Summary: 1902.*

Number of quarries	26
Number of operators	20
Salaried officials, clerks, etc.:	
Number	35
Salaries	$27,228
Wage-earners:	
Average number	335
Wages	$149,114
Contract work	100
Miscellaneous expenses	$18,776
Cost of supplies and materials	$38,386
Product:	
Quantity (short tons)	445,903
Value	[1] $421,289

[1] The United States Geological Survey reports under "glass sand" (which is not included with the statistics for stone) 943,135 short tons, valued at $807,797, which includes glass sand obtained from banks. Census figures include only the sand produced at sandstone quarries by crushing the rock.

Of the 26 quarries, 10 were in Ohio, 14 in Pennsylvania, and 2 in West Virginia, the statistics of the last named being included with those of Pennsylvania to avoid disclosing the business of individual operators. These quarries were controlled by 20 operators, 5 of whom were individuals, 5 firms, and 10 incorporated companies; 7 of these companies were reported from Pennsylvania.

Employees and wages.—The 335 wage-earners constituted 90.5 per cent of the salaried employees and wage-earners, and the $149,114 paid as wages was 84.6 per cent of the total salaries and wages. The average number of wage-earners employed each month is shown in the detailed summary, Table 41. The greatest number, 380, was reported for September, and the least, 264, for February. This table shows also the average number of wage-earners at specified daily rates of pay by occupations. Of the 335 wage-earners, 261, or 77.9 per cent, were reported as receiving from $1.25 to $1.74 per day. There were 149, or 44.5 per cent, employed as quarrymen at rates ranging from 75 cents to $2.24 per day. The crushing of the stone entailed the employment of a large number of laborers and other workmen, who were reported as "all other wage-earners" and numbered 154, or 46 per cent, of the total. Silica sand is the only subdivision of the stone industry in which no boys under 16 years of age were reported.

Supplies, materials, and miscellaneous expenses.—Supplies and materials costing $38,386 were reported, $13,598, or 35.4 per cent of the total, having been expended in Ohio. The miscellaneous expenses amounted to $18,776, of which $8,373, or 44.6 per cent, was for royalties and rent of quarrying plants, and $10,403, or 55.4 per cent, for rent of offices, insurance, and other sundries. Of the total, $11,210, or 59.7 per cent, was reported from Pennsylvania and West Virginia, and $7,566, or 40.3 per cent, from Ohio.

Mechanical power.—The total power owned was reported as 2,000 horsepower, of which 805 was reported from Ohio and 1,195 from Pennsylvania. Of this total, 1,980 horsepower was supplied by 33 steam engines, 16 of which were in Ohio.

Production.—The United States Geological Survey has not published annual statistics of glass sand except for 1885 and 1902, and these statistics are not comparable with those of the census, because they include sand from pits and banks as well as that crushed at sandstone quarries.

Chief among the sand producing states, in 1902, was Pennsylvania, where sand was found in all forms. This state was followed closely by Ohio, where deposits were generally those of sandstone requiring crushing and screening. A small quantity was reported from West Virginia.

The 16 quarries shown for Pennsylvania (including the 2 in West Virginia) produced 312,982 tons, or 70.2 per cent of the total production, the value being $269,015, or 63.9 per cent of the total value. Of this amount, 127,520 tons, valued at $105,367, was glass sand; 31,500 tons, valued at $24,000, building sand; 15,241 tons, valued at $18,896, furnace sand; and 138,721 tons, having a value of $120,752, was consumed for other purposes.

The 10 quarries in Ohio produced 132,921 tons, or 28.1 per cent of the total quantity; the value was $152,274, or 36.1 per cent of the total value. Of this quantity, 60,396 tons, valued at $59,348, was furnace sand; 20,036 tons, valued at $24,896, glass sand; 3,750 tons, valued at $3,000, engine sand; and 48,739 tons, valued at $65,030, was used for other purposes.

Occurrence.—Silica or siliceous sand is known to exist in several states as a sandstone, requiring crushing and screening; as a stone that readily disintegrates when exposed to the action of the elements, and needs only washing or burning to reduce the amount of organic matter and other impurities; or as beds of pure sand, requiring no treatment to prepare it for use.

Sand used in the manufacture of glass consists mainly of silica with alumina, and it may be iron, soda, lime, and potash in small and varying quantities. The value of the sand depends on its freedom from such impurities as tend to produce a discoloration of the glass.

A summary presenting detailed statistics of the silica sand industry, by states, for 1902, is given in Table 41.

PLATE VII.—GRANITE QUARRY AT CROTCH ISLAND, MAINE (TWO VIEWS).

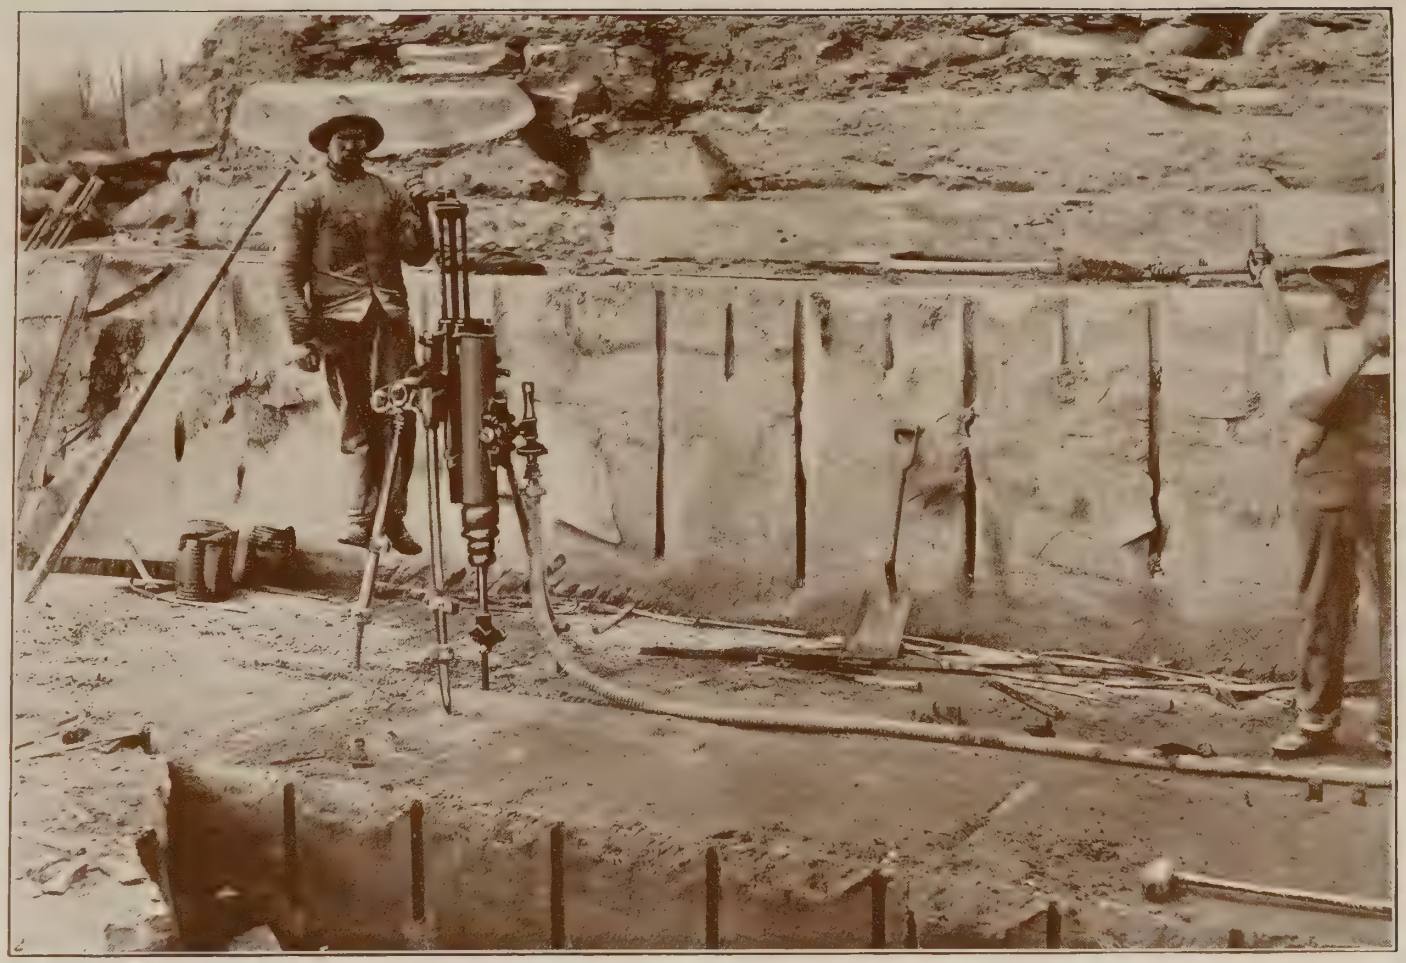

PLATE VIII.—STEAM DRILL USED IN STONE QUARRYING.

SILICEOUS CRYSTALLINE ROCKS.

Under this classification is grouped a somewhat variable series of rocks, including not merely the true granites, but also the gneisses (the so-called striped, stratified, or bastard granites of the quarrymen), the syenites, the black granites or traps (diabases and gabbros), diorites, basalts, and andesites, and, in a few instances, the mica schists.

The varying mineral character and structural features of these rocks are noted below:

Granite.—A crystalline, granular, massive rock, consisting essentially of quartz, orthoclase, and mica or hornblende, with other minerals, as apatite and magnetite occurring in microscopic quantities.

Gneiss.—A rock differing from granite in that the various constituents are arranged in more or less parallel layers, giving the rock a banded or foliated appearance. It is often called stratified or bastard granite by the quarrymen.

Syenite.—A rock, limited in quantity, differing from granite only in the absence of quartz as an essential constituent, i. e., one consisting of orthoclase with one or more of the minerals of the mica, amphibole, or pyroxene group.

Elaeolite (nepheline) syenite.—A rock differing from syenite in that the mineral elaeolite (nepheline) wholly or in part replaces the feldspar. The "granite" near Hot Springs, Ark., is a good example of this rock.

Diabase and gabbro.—Rocks consisting essentially of augite or hypersthene and plagioclase feldspars with accessory apatite, magnetite, and frequently black mica. These are hard and massive rocks, often very dark gray to almost black in color, and in the case of the gabbro at Pleasant river, Me., known as black granite. In the majority of cases they are used only for road material.

Diorite.—A rock consisting essentially of hornblende or mica and plagioclase feldspar with other minerals in smaller proportions. In America this rock is little used for building material.

Basalt.—A lava composed essentially of augite and plagioclase feldspar. It occurs mainly in the Western states.

Andesite.—A rock composed of augite or hornblende and plagioclase feldspar. It is a lava, and its occurrence is limited mainly to the Western states.

Mica schist.—A rock composed essentially of quartz and mica, but with a pronounced schistose structure. It is little used for general building owing, in part, to its poor working qualities.

The statistics for siliceous crystalline rocks were separately presented at the censuses of 1880 and 1889. In the following table the statistics for these years and those for 1902 are shown for the purpose of comparison:

TABLE 26.—*Comparative summary: 1880 to 1902.*

	1902	1889	1880
Number of quarries	906	874	313
Number of operators	853	814	[1]
Salaried officials, clerks, etc.:			
Number	1,377	[2] 222	[1]
Salaries	$1,227,885	[3]	[1]
Wage-earners:			
Average number	18,836	[2] 22,091	[4] 11,477
Wages	$11,072,996	[3] $9,620,485	[1]
Miscellaneous expenses	$810,206	$437,051	[1]
Cost of supplies and materials	$2,493,065	$1,446,485	[5] $70,397
Value of product	$18,257,944	$14,464,095	$5,188,998

[1] Not reported.
[2] Foremen included in wage-earners.
[3] Salaries included in wages.
[4] Greatest number employed.
[5] Value of explosives.

The increase in the number of quarries was 561, or 179.2 per cent, from 1880 to 1889, and 32, or 3.7 per cent, from 1889 to 1902. This difference in percentage of increase is due partly to the tendency toward combination noted in the discussion of Table 2. The value of the product of these quarries increased $9,275,097, or 178.7 per cent, from 1880 to 1889, and $3,793,849, or 26.2 per cent, from 1889 to 1902.

Development work was reported at 4 quarries located 1 each in California, Connecticut, Missouri, and New York. These quarries were controlled by 4 operators, 3 of them being incorporated companies. The capital stock and bonds issued by 2 of these companies amounted to $19,500. These 4 quarries gave employment to 83 wage-earners, who received $44,640 in wages.

There were 313 quarries reported idle during 1902. These were controlled by 313 operators.

Employees and wages.—The total number of salaried officials, clerks, etc., and wage-earners was 20,213, and they received $12,300,881 in salaries and wages. The wage-earners formed 93.2 per cent of this number, and their wages amounted to 90 per cent of the total.

Table 27 presents the average number of wage-earners employed during each month.

TABLE 27.—*Average number of wage-earners employed during each month: 1902.*

MONTH.	Wage-earners.
January	12,442
February	12,828
March	14,933
April	18,882
May	20,350
June	21,589
July	22,678
August	22,843
September	22,331
October	22,019
November	19,348
December	15,789

The foregoing table shows that the number of employees was greatest in August, when 22,843 wage-earners were given employment, and the least in January, for which month 12,442 were reported. This

inconstancy of operation is explained in the discussion of Table 4.

The following table shows, for the several classes of employees, the number receiving certain specified rates of pay, and also the percentages which these numbers form of the total number in the class:

TABLE 28.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY OCCUPATIONS: 1902.

RATE PER DAY (DOLLARS).	ALL OCCUPATIONS.		ENGINEERS.		FIREMEN.		MACHINISTS, BLACKSMITHS, CARPENTERS, AND OTHER MECHANICS.		QUARRYMEN AND STONECUTTERS.		BOYS UNDER 16 YEARS.		ALL OTHER WAGE-EARNERS.

4.25 and over	9	0.1	.....	.....	.....	.....	.....	.....	9	0.1	.....	.....	.....	.....

[1] Includes 528 wage-earners paid in accordance with the amount of work done, for whom average daily earnings are shown.
[2] Less than one-tenth of 1 per cent.

The figures presented in the above table indicate a wide range in the daily rates of pay. Of the total number reported, 743, or 3.9 per cent, received less than $1 per day, and 836, or 4.5 per cent, received $3.25 per day or over. For the remaining 17,257 wage-earners, constituting 91.6 per cent of the total number, the range of wages was from $1 to $3.24 per day.

About three-fourths (76.8 per cent) of all the wage-earners reported were classified as quarrymen and stonecutters. Their rates conform very closely to those for all occupations combined, 92 per cent of the total number having received between $1 and $3.24 per day, as compared with 91.6 per cent for all occupations combined. An examination of the figures for quarrymen and stonecutters shows a marked concentration at the rates from $1.25 to $2.24 per day, then a slight falling off, and again a concentration for the rates from $2.75 to $3.24 per day. This indicates the difference between the rates paid to quarrymen and those paid to stonecutters, who are more skilled than the quarrymen.

There were 658 engineers reported, of whom 503, or 76.4 per cent, received between $1.75 and $2.74 per day. The range of wages for 65.8 per cent of the firemen was from $1.25 to $2.24 per day, 9.8 per cent having received less than $1.25, and 24.4 per cent, $2.25 or over. Rates were considerably higher for machinists and other mechanics, three-fourths of them having been paid from $2.00 to $3.24 per day.

The number of boys under 16 years reported was 206, of whom 91 were in the New England states and 46 were in South Carolina and Georgia. The rates of pay for 164 of these boys were between 50 cents and $1.24 per day; of the others, 36 received less than 50 cents and 6 received $1.25 or over.

The group of "all other wage-earners" includes 2,240 men, or 11.9 per cent of the total number of wage-earners reported. The range of wages for 2,029 of them was from 75 cents to $2.24 per day. The number receiving $1.50 per day was probably greater than that at any other rate, since the wage group, $1.50 to $1.74, includes a much larger number than is included in any other group.

Supplies, materials, and miscellaneous expenses.—The total cost of supplies and materials was $2,493,065. Of this amount $509,702, or 20.5 per cent, was expended in Massachusetts; $272,888, or 10.9 per cent, in Vermont; and $217,548, or 8.7 per cent, in Maine. Smaller amounts were reported from the other states.

The amount paid for royalties and rent of quarrying plants was $194,892, or 24.1 per cent of the total, and $615,314, or 75.9 per cent, was paid for rent of offices, taxes, and other sundries.

Mechanical power.—Primary power aggregating 46,986 horsepower was reported; 44,189, or 94 per cent, was applied through 950 steam engines; 275, or six-tenths of 1 per cent, was generated by 26 gas or gasoline engines; and 1,506, or 3.2 per cent, by 15 water wheels. Under "other power," 510 horsepower, or 1.1 per cent, was reported. The rented horsepower was 506, or 1.1 per cent, of which 471 was electric. In addition, 23 electric motors, having a capacity of 442 horsepower, were owned by the operators reporting them.

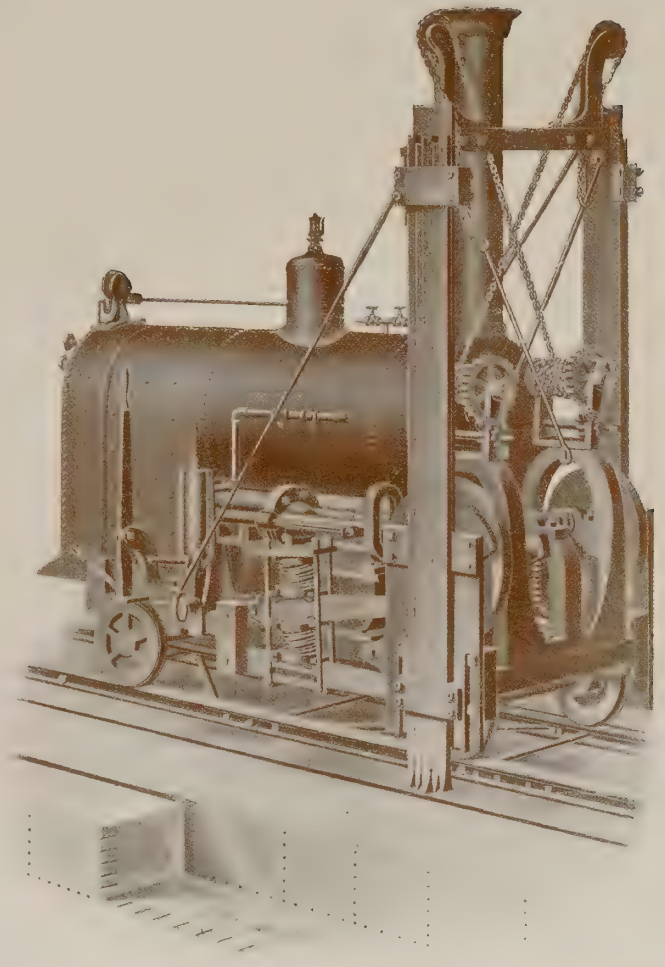

PLATE IX.—DOUBLE GANG MARBLE AND LIMESTONE CHANNELING MACHINE.

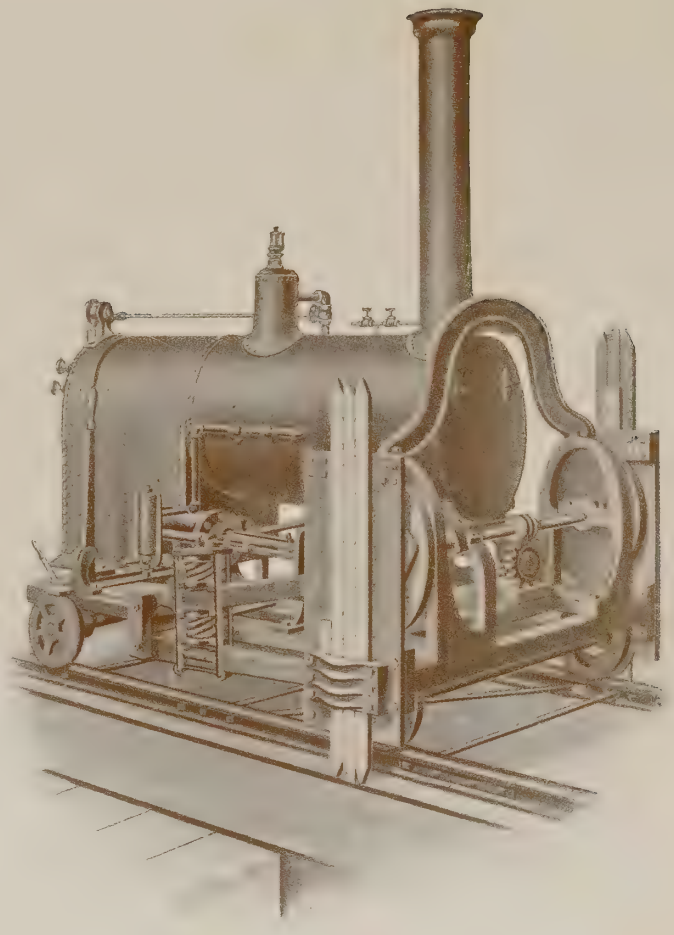

PLATE X.—DOUBLE GANG SANDSTONE CHANNELING MACHINE.

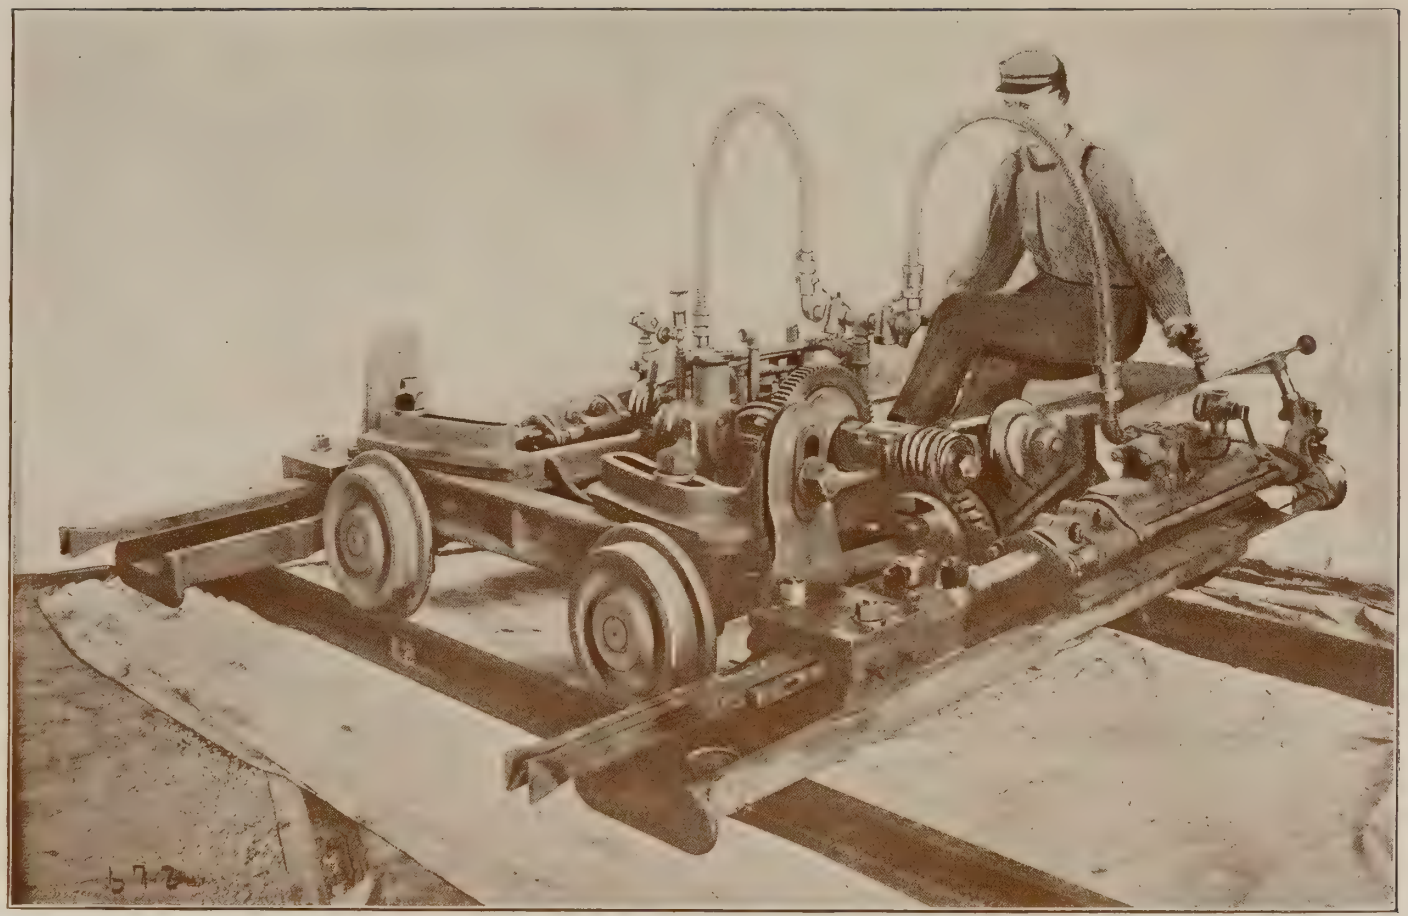

PLATE XI.—CHANNELING MACHINE FOR UNDERCUTTING.

Production.—The following table shows the production of siliceous crystalline rocks, classified by uses, 1896 to 1902:

TABLE 29.—VALUE OF ANNUAL PRODUCTION OF SILICEOUS CRYSTALLINE ROCKS, CLASSIFIED BY USES: 1896 TO 1902.

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	VALUE OF PRODUCT.						
	Rough, all uses.	Dressed.		Made into paving blocks.	Curbing.	Crushed, all uses.	All other uses.
		Building.	Monumental.				
1896	$2,232,682	$2,232,077	$1,437,065	$1,231,729	$166,392	$514,550	$130,499
1897	2,363,031	2,565,636	1,414,502	1,140,417	160,195	991,867	269,427
1898	1,826,865	1,874,980	1,462,598	854,151	583,407	1,592,925	1,129,480
1899	2,351,931	2,625,289	1,687,967	969,499	545,655	2,044,797	1,393,201
1900	2,455,276	3,233,224	1,598,842	1,006,296	593,209	2,571,899	1,216,871
1901	3,486,574	3,781,294	1,457,557	1,821,431	670,703	3,003,443	1,755,959
1902	[1] 4,433,152	4,859,750	2,284,755	1,523,776	823,846	3,211,780	1,120,885

[1] Includes building stone valued at $2,175,082, monumental stone valued at $1,714,156, and stone for other uses valued at $543,914.

Of the total value of product, $18,257,944, in 1902, a value of $7,034,832 was used for building purposes and $3,998,911 for monumental work. The remaining material to the value of $7,224,201 was utilized for a variety of purposes, but especially for paving blocks and as crushed stone for macadam. The introduction of machinery has rendered possible the utilization of the granites and other hard rocks in monumental work to an extent that was quite impossible when the stone was dressed by hand. The use of stone for macadam is largely a development of the past twenty years, and the demand for it for this purpose has caused the great increase in the number of quarries of trappean rock. This demand for crushed stone likewise enables the quarries worked mainly for building or monumental stone to dispose of their waste. The material used for macadam depends, however, to a considerable extent on the kind of rock that is available in neighboring sources. While the trappean rocks have proved most desirable for this purpose, the total absence of material of this type from the great interior Mississippi valley has caused the substitution largely of limestone and, in some cases, of sandstone.

The following table shows the value of product of siliceous crystalline rocks from 1890 to 1902:

TABLE 30.—*Value of annual production of siliceous crystalline rocks: 1890 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	Value of product.	YEAR.	Value of product.
1890	$14,464,095	1897	$8,905,075
1891	13,867,000	1898	9,324,406
1892	12,642,000	1899	11,618,339
1893	8,808,934	1900	12,675,617
1894	10,029,156	1901	15,976,961
1895	8,894,328	1902	18,257,944
1896	7,944,994		

The value of the product decreased from 1890 to 1894, then increased, declining again in 1895 and 1896, since which time it has constantly increased.

As shown in Table 42, there were 204 quarries in Massachusetts and 110 in Maine. The number of quarries in the other states varied from 74 in Vermont to 1 each in Arizona and Nevada. Indian Territory also reported 1. In the following comparative table the values of the products for 1902, 1889, and 1880 are given, and the states are ranked according to these values.

TABLE 31.—*Production of siliceous crystalline rocks, by principal states ranked by value of product: 1902, 1889, and 1880.*

STATE.	1902		1889		1880	
	Value.	Rank.	Value.	Rank.	Value.	Rank.
Massachusetts	$3,451,397	1	$2,503,503	1	$1,329,315	1

Massachusetts and Maine occupied in 1902 the same relative position that they held at the Tenth and Eleventh censuses. California, however, dropped from the third to the fifth place in the list, while Vermont advanced from the ninth to the third, and New Hampshire from the seventh to the fourth. The changes in rank are due in some cases to a decrease in production, as in the case of California, and in others to an increase, as in the case of Vermont and New Hampshire. Georgia, which made such a remarkable increase between

the Tenth and Eleventh censuses, causing it to advance from twelfth to sixth in rank, has dropped to eighth, although there has been an actual increase in the product.

The detailed statistics of the industry for 1902 are given in Table 42.

During the early history of the industry, when railroads were few, transportation of material as heavy as stone was largely by water. Hence it naturally followed that quarries situated close to the water's edge, like those of Vinalhaven and Crotch Island, Me. (see Plate VII), had a great advantage, and for a long time practically controlled the market. With the multiplicity of railroads, however, and the growing demand of inland cities remote from waterways, inland quarries at first wholly inaccessible have become important factors, and as a consequence the coast states have, to a considerable extent, lost prestige.

Of the quarries developed during the last decade, on account of the quality as well as quantity of material they furnish, those in the vicinity of Barre, Vt., and Montello, Wis., are of greatest interest. The quarry near Montello furnishes a beautiful, compact, dark red-brown granite admirably adapted for monumental work.

SLATE.

The materials brought together in this report under the head of slate are argillaceous rocks, which, through the process of shearing and incidental chemical activity, have undergone a partial metamorphism, resulting in the development of a pronounced tendency to split along certain planes, which may or may not be parallel with the original bedding, into thin sheets suitable for roofing purposes. It is necessarily a consequence that such are restricted to the regions of pronounced earth movements, such as have resulted in the formation of mountain ranges.

The decrease in the number of quarries since 1889 has not been attended by a decrease in any of the other items and is largely due to consolidation of interests.

The apparent decrease in the number of wage-earners is due to the methods employed by the various censuses in finding the average and in part to the introduction of machinery. The steady increase in the amount paid as wages indicates that the difference shown in the "average number" is not due to an actual decrease in the number of wage-earners. The production increased $2,213,538, or 63.6 per cent, from 1889 to 1902.

Census statistics for slate quarries were shown as early as 1850, when the value of product was reported as $29,056, the number of quarries being 5. At the census of 1860, there were 22 quarries, with a production valued at $287,150. The census of 1870 was the first at which the mining industries were separately shown. The following comparative summary includes the statistics from 1870 to 1902:

TABLE 32.—*Comparative summary: 1870 to 1902.*

	1902	1889	1880	1870
Number of quarries	199	212	94	(1)
Number of operators	174	(1)	(1)	[2]101

[1] Not reported.
[2] Establishments.
[3] Foremen included in wage-earners.
[4] Salaries included in wages.
[5] Greatest number employed.
[6] Value of explosives.

There were 3 quarries, all in Pennsylvania, for which development work was reported for 1902. One salaried employee received a salary of $900 and 13 wage-earners were paid $4,952 in wages.

The total capital stock and bonded indebtedness in the slate industry amounted to $11,323,565, of which Pennsylvania reported $3,356,940, or 29.7 per cent; Maine, $1,645,800, or 14.5 per cent; New York, $1,018,500, or 9.0 per cent; Maryland, $316,300, or 2.8 per cent; Vermont, $275,600, or 2.4 per cent; New Jersey, $77,000, or seven-tenths of 1 per cent; and all other states $4,633,425, or 40.9 per cent.

Employees and wages.—There were 6,357 salaried employees and wage-earners, who were paid $3,512,338; of this number the 5,920 wage-earners formed 93.1 per cent, and the $3,177,459 paid them in wages was 90.5 per cent of the total salaries and wages.

The following table shows the average number of wage-earners employed during each month:

TABLE 33.—*Average number of wage-earners employed during each month: 1902.*

MONTH.	Wage-earners.
January	5,265
February	5,302
March	5,468
April	5,898
May	6,136
June	6,143
July	6,302
August	6,353
September	6,344
October	6,223
November	5,947
December	5,659

The largest number of wage-earners, 6,353, was reported for August, and the least, 5,265, for January, a variation of 1,088.

In the following table, the distribution of wage-earners, according to daily rates of pay, is given by occupations:

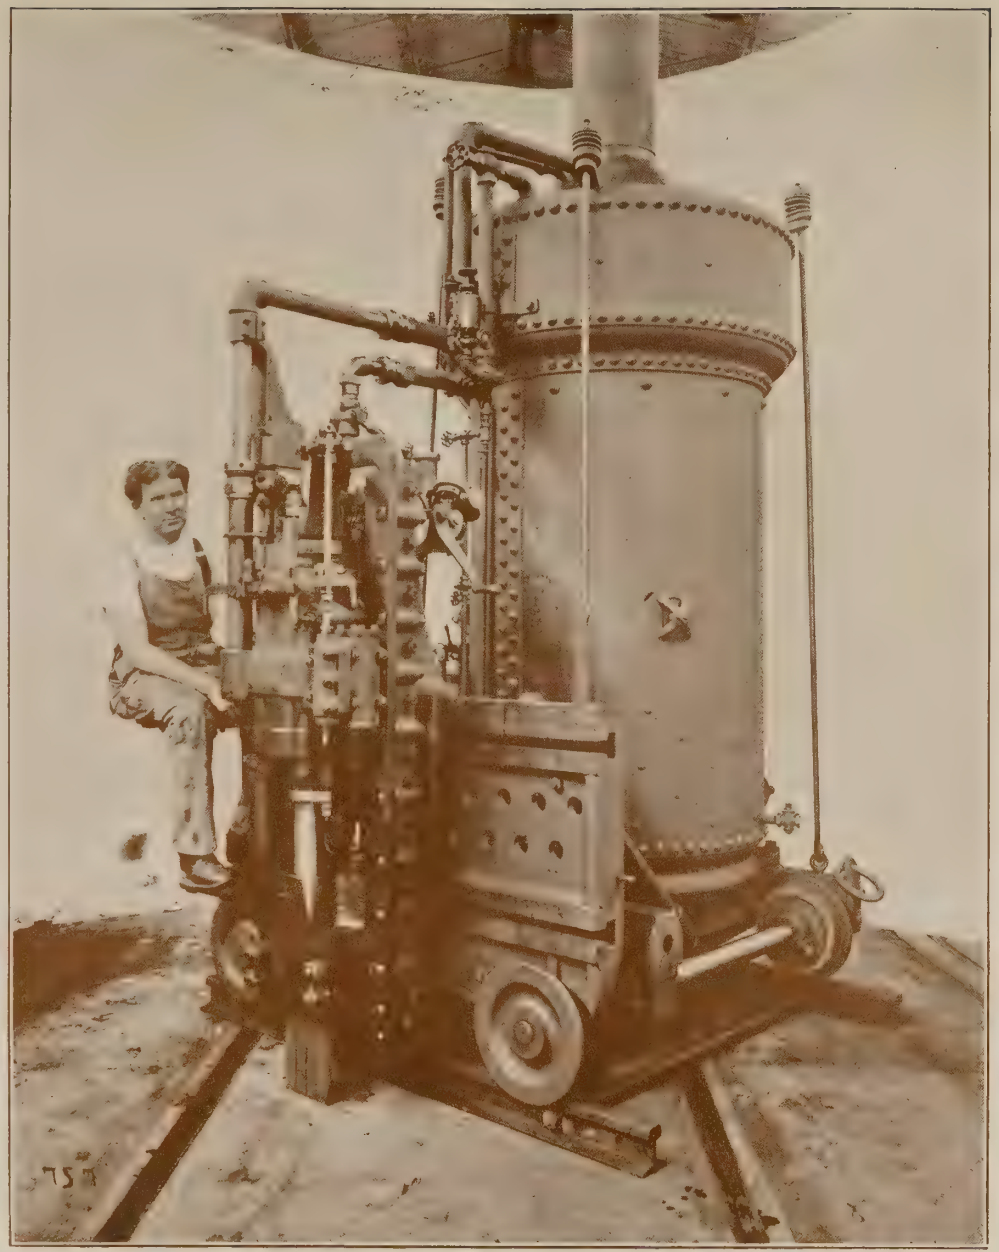

PLATE XII.—TRACK CHANNELER, WITH BOILER.

[1] Includes 800 wage-earners paid in accordance with the amount of work done, for whom average daily earnings are shown.
[2] Less than one-tenth of 1 per cent.

As shown by the above table, the range of wages for practically all of the employees in slate quarries was from $1 to $2.74 per day, 5,465, or 92.3 per cent of the total number, having been reported at rates between those limits.

Quarrymen and stonecutters to the number of 3,656 were reported. Of these 2,853, or 78 per cent were paid from $1.50 to $2.49 per day. Of the remainder 302, or 8.3 per cent, received between $1 and $1.49 per day, and 491, or 13.4 per cent, received from $2.50 to $3.24. Probably a greater number were employed at $2 per day than at any other single rate, as the group $2 to $2.24 includes 1,160 men, constituting 31.7 per cent of the total number.

The range of wages for 228 engineers, 81.7 per cent of the total number reported, was between $1.25 and $2.24 per day, and of the 87 firemen, 71 were included between the same rates. The rates of pay for 118 machinists and other mechanics, out of a total of 137, were between $1.50 and $2.74 per day.

The boys under 16 years employed in slate quarries in 1902 numbered 169. Of these, 115 were reported from Pennsylvania and 38 from Vermont. The rates for 141 of these boys, constituting 83.5 per cent of the whole number, were between 50 and 99 cents per day.

The group of "all other wage-earners" formed slightly more than one-fourth of all the wage-earners reported. Their wages ranged from 50 cents to $3.74 per day, but 74.7 per cent of them received from $1.25 to $1.74, the proportion at lower or higher rates being comparatively small.

The following table shows the distribution of wage-earners according to daily rates of pay, by states:

TABLE 35.—DISTRIBUTION OF WAGE-EARNERS ACCORDING TO DAILY RATES OF PAY, BY PRINCIPAL STATES: 1902.

[Each cumulative percentage shows the proportion of the total number receiving a wage as great as, or greater than, the lowest wage of the given wage group.]

[1] Less than one-tenth of 1 per cent.

In the above table separate statistics are presented for Pennsylvania and Vermont only. These two states gave employment to 5,065 wage-earners, or 85.6 per cent of the total number employed in slate quarries in the United States. On the whole, there was comparatively little difference between the rates of pay in the two states. The range of wages for the bulk of employees was greater in Pennsylvania than in Vermont. In the latter state 76.3 per cent of the wage-earners received between $1.50 and $2.24 per day, while in Pennsylvania only 42.1 per cent were included within those rates. In Pennsylvania, on the other hand, there were 28.7 per cent receiving less than $1.50, as compared with 11.9 per cent in Vermont, and 29.2 per cent receiving $2.25 or over, as compared with 11.8 per cent in Vermont.

The 855 wage-earners reported under "all other states" were scattered through 7 states, the number reported in the individual states being too small to warrant separate presentation. It will be seen, however, that taking these states as a group the rates of pay were lower than those for either Pennsylvania or Vermont.

Supplies, materials, and miscellaneous expenses.—The total amount expended for supplies and materials was $680,361; of this amount Pennsylvania reported 61.4 per cent; Vermont, 23.9 per cent; Maine, 4 per cent; Virginia, 3.1 per cent; Maryland, 2.6 per cent; New York, 2.4 per cent; and all other states 2.6 per cent.

Of the total miscellaneous expenses $269,267, or 60.4 per cent was paid for royalties and rent of quarrying plants, and $176,878, or 39.6 per cent, for rent of offices, taxes, and other sundries.

Mechanical power.—The total horsepower reported was 25,454; of this amount 24,649, or 96.8 per cent, was applied through 599 steam engines; 425, or 1.7 per cent, was furnished by 5 water wheels; 185, or seven-tenths of 1 per cent by other mechanism; and 195, or eight-tenths of 1 per cent, was rented electric power.

Production.—In the following table the annual production of slate is classified by uses for the years from 1890 to 1902:

TABLE 36.—*Value of annual production of slate, classified by uses: 1890 to 1902.*

[United States Geological Survey, "Mineral Resources of the United States."]

YEAR.	PRODUCT.			
	Total value.	Roofing slate.		Mill stock.
		Number of squares.	Value.	Value.
1890	$3,482,513	835,625	$2,797,904	$684,609
1891	3,825,746	893,312	3,125,410	700,336
1892	4,117,125	953,000	3,396,625	720,500
1893	2,523,173	621,939	2,209,049	314,124
1894	2,790,324	738,222	2,301,138	489,186
1895	2,698,700	729,927	2,351,509	347,191
1896	2,746,205	673,304	2,263,748	482,457
1897	3,524,614	1,001,448	3,097,452	427,162
1898	3,723,540	916,239	3,129,390	594,150
1899	3,962,733	1,100,513	3,454,817	507,916
1900	4,240,466	1,194,048	3,596,182	644,284
1901	4,787,525	1,304,379	4,114,410	673,115
1902	5,696,051	1,435,168	4,950,428	745,623

The year of greatest depression was 1893, when the value of the product was $2,523,173. There was an increase in 1894, but a slight decrease in 1895. A gradual increase followed from that time until 1902, when the value of all slate produced was $5,696,051. Of this output material to the value of $4,950,428 was utilized for roofing, and the remainder, to the value of $745,623, for minor purposes. It is worthy of note that in 1890 the value of the slate utilized for roofing purposes was $2,797,904, and that for all other purposes, $684,609. This indicates that no important new uses for slate have been found and that developments have been largely in the line of roofing materials.

Ranked by value of product first place was held by Pennsylvania, second by Vermont, and third by Maine, followed by Virginia, New York, and Maryland in the order named.

Table 43, at the end of this report, presents detailed statistics of the industry for 1902.

Occurrence.—Nearly the entire commercial supply of roofing slates comes from states bordering upon the Appalachian mountain system. The prevailing color of the material is of a blue-gray to nearly black tint, though certain of the Vermont quarries produce a green and purplish slate. The supply of red slate is at present limited wholly to a few quarries in eastern New York.

Except in California, there have been during the past ten years no developments of great significance, long established quarries in the states mentioned still furnishing the major part of the material. The quarries in Maine are situated wholly in Piscataquis county, those in Vermont along the western part of the state, bordering on the New York line, the developments of particular note being in the towns of Castleton, Fair Haven, Pawlet, Poultney, and Wells. In New York they are found in the closely adjacent towns of Granville and Middle Granville and other towns in Washington county. The slates of New Jersey occur in Sussex and Warren counties; in Pennsylvania, particularly in Lehigh, Northampton, and York counties. The Maryland output is still derived wholly from the northern part of Harford county, in the well known Peach Bottom area.

Uses.—The slates are utilized to a very large extent for the production of roofing materials, for which purpose they are split into sheets from one-eighth to three-sixteenths of an inch in thickness and trimmed into rectangular slabs varying in size from 3 by 7 to 14 by 24 inches. The price of these slabs is usually dependent upon the number required for a "square," that is, a space 10 feet square, or containing an area of 100 square feet. Besides being used for roofing, slates are utilized for billiard tables, mantels, floor tiles, steps, flagging, blackboards, sinks and stationary washtubs, electrical switchboards, and in the manufacture of school slates and pencils. Incidentally it may be mentioned that there has of late years been something of a demand for roof-

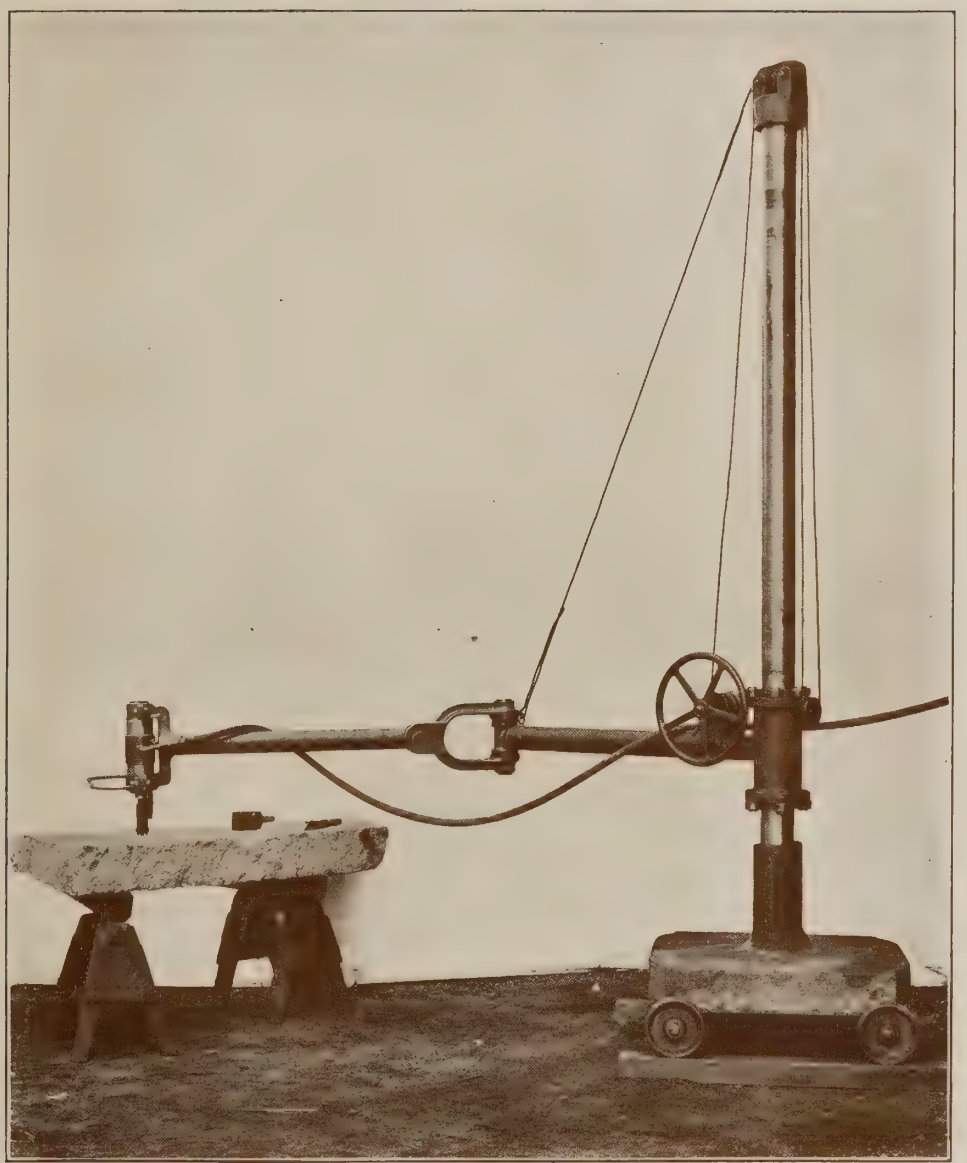

PLATE XIV.—PNEUMATIC STONE SURFACING MACHINE.

PLATE XV.—LARGE GRANITE COLUMN-CUTTING LATHE AT VINALHAVEN, MAINE.

ing slates of such thickness as to simulate tiles, some of the quarries actually furnishing material split into sheets of the ordinary sizes, but 1 inch or more in thickness. The practice of "marbleizing" slate for mantels has been largely discontinued.

QUARRYING AND STONE DRESSING MACHINES.

In the earlier days of the stone industry hand methods were employed almost exclusively in the work of quarrying and dressing. The past twenty years has, however, witnessed the introduction of machinery at a rate which is probably fully comparable with that in any other industry. The old method of drilling and blasting, formerly applied to all classes of rocks, is now done away with excepting in the very hardest and toughest of materials, or where, as in the case of the trappean rocks, the material is to be utilized only for road metal. Even where drilling and blasting are now resorted to, it is the custom to drill a series of holes in the line along which it is desired the stone shall break; these holes are then charged somewhat lightly and fired simultaneously. In this way the force of the explosion is delivered along a considerable surface and the danger of shattering the material through the sudden jar is reduced to a minimum. This process is at present largely limited to granitic rocks which are too hard to be quarried by means of the channeling machines.

The drill commonly employed for this work consists in its simplest form of a steam cylinder, mounted upon a tripod, with the drill attached directly to the piston. Since a flexible hose is used to convey steam from the boiler, this form of drill can be carried to any part of the quarry. Numerous adaptations of this drill have been put upon the market by various makers. A common form is that shown in Plate VIII. On soft stone, like sandstone, or granitic rocks with well-developed rift and grain, drills of this kind are utilized in what is known as plug-and-feather splitting. Here a series of holes of a diameter and depth depending upon the character of the rock are drilled at intervals along the line at which it is desired to break the stone. Long metal wedges or plugs are then driven into the holes and the material is split away in fairly regular blocks. This method is used to a considerable extent in the harder Ohio sandstones. During the census year, 3,847 steam drills of various makes were reported as in use.

Channeling machines are utilized in the case of rocks of the nature of marble, limestone, and the softer sandstone, since they would be liable to injury through blasting, and since it is desired to remove the materials from the quarry bed with a minimum amount of waste and in such size and shape that they may be cut into suitable dimensions. One of the earliest of these machines upon the market was the Wardwell channeling machine, a cut of which is shown in Plate IX. Various modifications of this have since been made, as shown in Plates X, XI, and XII. These later adaptations make it possible to cut a channel at any desired angle. There were 724 of these machines of various makes reported in use during the census year. What is known as the quarry bar, answering the same purpose as the channeling machine, but without the locomotive attachment, is shown in Plate XIII. A machine based on the same principle for undercutting, or gadding, is in common use in the marble quarries of Vermont. A diamond drill machine is used for similar purposes. There were 153 machines of various makes adapted to this work reported in operation during the census year.

An attempt has been made to introduce the so-called helicoidal saw for quarrying the softer rocks, as limestone and marble. The attempt seems to have been only partially successful, except in the larger limestone quarries of the Middle West, owing apparently to the large amount of labor necessary for putting the saw in position and the waste involved in cutting out the corners in which the pulleys are to run. The returns from all the quarries report only 32 of these saws actually in use. The saw, as is well known, consists of a twisted iron-wire rope, generally three-sixteenths of an inch in diameter, running over sliding pulleys, the abrading material being either sand or chilled iron, as the case may be.

After the stone is removed from the quarry bed it is worked into the desired shape and size by a process dependent largely upon the hardness of the stone. Formerly a block after being reduced to an approximately rectangular form by means of hand plug-and-feather splitting, was still further reduced by pitching tools, followed when necessary by such implements as the point, ax, pean hammer, and bushhammer. Pneumatic tools are gradually replacing these hand implements. What is known as the pneumatic surfacing machine is shown in Plate XIV. This and the other machines mentioned below are in use in the stone yards and workshops in towns and cities, as well as at the larger quarries, and statistics as to number are not available. Lathes and planers are utilized very extensively on the softer stones, and in some of the works on hard stones as well. Indeed, the production of cylindrical columns by the old hand method has been almost entirely superseded by the use of lathes similar to those used in turning metals. A monster machine of this type is shown in Plate XV. Specially adapted forms of lathes are also used in turning grindstones at the Ohio sandstone quarries. Planers thus utilized differ so little from those employed in planing metal that they need no special notice here. Attention should, however, be called to the circular planer which is used in working out curved surfaces. Except on the harder stone, like granite and quartzite, saws are extensively used for splitting up material into rectangular masses and slabs where smooth, even surfaces are desired. Those most in use are the old time reciprocating saws

consisting of a band of soft iron set in a frame and fed with sand, chilled iron, or shot, as the case may be. Circular saws are also utilized in some cases. A circular saw with diamond teeth is occasionally employed. In working slate a steel circular saw with teeth similar to that used in sawing lumber is employed. In handling the material in the yards and shops traveling cranes are used much as in iron and steel works.

TABLE 37.—DETAILED SUMMARY, BY CLASSES: 1902.

	Total.	Limestones and dolomites.	Marble.	Sandstones and quartzites.	Silica sand.	Siliceous crystalline rocks.	Slate.
